Introduction

The study of human behavior has always attracted the interest of economists, engineers, psychologists, planners, and marketing experts who have attempted to explain the past behavior via a behavioral analysis approach and predict future behavior via a predictive modeling approach. Discrete choice models are the foundation of the study of human behavior from both a behavioral perspective, where the analysis focuses on revealing features and anomalies of choice behavior, and a predictive perspective, where the analysis concentrates on emphasizing the regularities of choice behavior (Ben-Akiva et al., 2002).

Travel behavioral modelers have traditionally used discrete choice models for the purpose of explaining the past behavior and predicting the future behavior of travelers while relying on basic concepts from the neo-classical economic theory. Specifically, choice models are based on the concept of utility, a latent construct that captures the value that a decision-maker associates with the available alternatives, and a maximization principle, an abstraction of the decision-maker as a rational actor who chooses the alternative with the highest utility in the attempt to maximize their personal wellbeing. Utility is typically mapped as a function of observed characteristics of the decision-maker (e.g., gender, age, income) and the alternatives (e.g., travel time, public transport fare, tolls), and assumptions about the stochastic component of the function allows for the calculation of the probability of choosing an alternative among all the ones that are available to the decision-maker. However, it is plausible to think that choice behavior is not only determined from observed characteristics of the decision-maker and the alternatives that are easy to measure, but also by information processing, perceptions, attitudes, beliefs, context, external constraints as individual preferences are formed because of psychological and sociological reasons (McFadden, 1986). As recognized by psychologists, who have a greater interest in the behavioral analysis when compared to economists and engineers who have a greater interest in the predictive analysis, latent constructs such as attitudes, perceptions, norms, affects, and beliefs most likely influence the choice behavior of decision-makers (Bamberg and Schmidt, 2001; Gärling et al., 2003). Accordingly, models are needed to integrate these unobservable constructs within the mapping of the utility if we were to capture the determinants of choice behavior.

Three approaches were initially proposed in the literature to recognize the importance of unobserved characteristics of the decision-maker (e.g., attitudes, perceptions, norms) in the explanation of their choice behavior (Bhat and Dubey, 2014). The first approach used parametric or nonparametric random distributions to account for the intrinsic preference for alternatives and the sensitivity to attributes of the alternatives to vary across decision-makers (e.g., Bhat, 1998; Revelt and Train, 1996). However, the model estimation was econometrically inconsistent because the attitudes and perception might have been correlated with the observed variables that were used in the utility functions to explain the choice behavior. The second approach utilized indicators of attitudes as explanatory variables in the mapping of the utility (e.g., Bhat and Koppelman, 1993; Koppelman and Hauser, 1978). However, the model estimation was econometrically inconsistent because the indicators might have not been representing directly the underlying attitudes that are related to the choice and consequently have been generating a measurement error of the latent variables. The third approach applied factor analysis to reduce the number of indicators into a manageable number of latent variables that are "error-free" explanatory variables. However, the model estimation was econometrically inconsistent because the latent variables might have been specific to individual alternatives or might have interacted with variables that vary across alternatives.

More recently, the Integrated Choice and Latent Variable (ICLV) model (see Bolduc et al., 2005; Walker and Ben-Akiva, 2002) was proposed as an econometrically consistent answer to the need of incorporating attitudes, perceptions, norms, affects and beliefs into discrete choice models. The objective of the model was to gain a broader and deeper understanding of the choice behavior of decision-makers by combining observed variables with psychometric measures associated with individual attitudes, perceptions, etc. Advancements in behavioral and social sciences made the task easier thanks to the progress in the development of survey instruments (e.g., batteries of Likert scale items for rating the level of agreement or disagreement on a symmetric scale), which allowed to measure a large variety of latent variables that could relate to choice behavior, as well as the elaboration of decision-making theories, which provided a theoretical support to the study of choice behavior (see, e.g., Ajzen, 1991; Homer and

Figure 1 The ICLV model framework. Source: Adapted from Vij and Walker (2016).

Kahle, 1988; Triandis, 1977). The testing of both theories and scales relies often on variations of Structural Equations Modeling (SEM), which is suitable for capturing causal relations between a variety of observed and latent variables, but is less seemly for explaining choice behavior as it lacks the depth in that regard of the utility maximization framework at the foundation of discrete choice modeling. The ICLV model closes the methodological gap by combining the latent variable modeling used by behavioral and social scientists with the discrete choice modeling utilized by econometricians, hence removing all the restrictions related to the assumptions required for SEM estimation.

Given the purpose of gaining a broader and deeper understanding of choice behavior, the ICLV model is very important from the behavioral perspective as it provides the opportunity for recognizing that the role of latent variables in explaining travel behavior may be just as relevant as the one of observed variables that have been traditionally used in utility functions for a long time. However, questions exist about the effectiveness of the ICLV model from the predictive perspective, as studies exist that support the assumption that it enhances not only the explanatory power but also the predictive ability of models (Bolduc and Daziano, 2010; Temme et al., 2008), but also studies exist that express concerns about whether the framework is beneficial to predict behavior (Chorus and Kroesen, 2014; Vij and Walker, 2016). As basic questions remain unanswered about whether an ICLV model fits the data better than a model without latent variables, or whether estimates from an ICLV model help answer policy questions that are already answered to by a model without latent variables, the remainder of this chapter presents the framework in its conceptual and mathematical formulation, discusses the range of application, and considers the future of ICLV models.

Model Framework

The ICLV model framework is presented in Fig. 1. The model for the latent constructs of attitudes, perceptions, norms, affects, and/or beliefs has two components: (1) measurement equations capture the relations between indicator variables and latent constructs, and (2) structural equations express the relations between observed exogenous variables and latent constructs as well as between the latent constructs themselves. The latent variables are assumed to be measured by multiple indicators that can be observed on a continuous, ordinal, or nominal scale, and in the latter cases the measurement equations map the continuous latent constructs to the ordinal or nominal scale of the indicator variables (e.g., on Likert-type scales). The model for the choice behavior of the decision-maker has also two components: (1) measurement equations indicate which alternative is chosen among the available ones that the decision-maker is aware of, and (2) structural equations map the utility of the alternatives as functions of both observed and latent variables. The choice is assumed to be consistent with the paradigm (e.g., utility maximization, regret minimization) that the decision-maker follows to choose the preferred alternative (e.g., the one with associated the highest utility, the one with associated the minimum regret).

Mathematically, four sets of equations represent the described components of the ICLV model (Vij and Walker, 2016):

$$I_n = Dx_n + \Gamma x_n^* + \eta_n \quad (1)$$

$$x_n^* = Ax_n + \nu_n \quad (2)$$

$$y_{ni} = \{1 \text{ if } u_{ni} \geq u_{nj} \text{ for } j \in \{j \dots J\}, 0 \text{ otherwise}\} \quad (3)$$

where x_n is the $(K \times 1)$ vector of observed variables, x_n^* is the $(M \times 1)$ vector of latent variables, I_n is the $(R \times 1)$ vector of indicators to measure the latent variables, u_n is the $(J \times 1)$ vector of utilities of each of the alternatives as perceived by decision-maker n , D is the $(J \times M)$ matrix of parameters and η_n is the $(R \times 1)$ vector of error terms of the measurement equations (1) of the latent variable model, A is the $(M \times K)$ matrix of parameters and ν_n is the $(M \times 1)$ vector of error terms of the structural equations (2) of the latent variable model, y_{ni} is the choice indicator equal to 1 if n chooses alternative i in the measurement equations (3) of the choice model,

and $\mathbf{B}$ and $\mathbf{\Gamma}$ are the $(J \times K)$ and $(J \times M)$ matrices of parameters and ε_n is the $(J \times 1)$ vector of error terms of the utility functions (4) of the choice model.

While the framework is conceptually easy to comprehend and its mathematical representation is econometrically consistent, the use of ICLV model is not straightforward for three reasons (Bhat and Dubey, 2014): (1) restrictions in the specifications used in applications; (2) difficulties in the estimation of the models; (3) computational requirements of the models. Initial applications of the ICLV model assumed that there was no correlation between the error terms of the structural equations of the latent variable model (i.e., the elements of vector ν_n) as well as between the error terms of the utilities of the alternatives in the choice model (i.e., the elements of vector ε_n). However, these assumptions were restrictive as there might have been unobserved factors that impact the formation of multiple attitudes for the same decision-maker or capture correlation for different alternatives (Temme et al., 2008). Also, most applications of the ICLV model used simulated maximum likelihood for model estimation, similarly to mixed logit models. However, the demands of integrating over a mixture of probabilities routinely causes convergence problems and increases computational times. Accordingly, more recently, a Bayesian Markov Chain Monte Carlo simulation approach (Daziano and Bolduc, 2013a) and a maximum approximate composite marginal likelihood (MACML) inference approach (Bhat and Dubey, 2014) were proposed to simplify the estimation of ICLV models and reduce the dimensionality of the integral.

Relevantly, significant advancements in optimization techniques and conspicuous improvements in computational power have contributed to the increase in the number of applications of the ICLV model. Even more relevantly, the availability of estimation software such as Biogeme (Bierlaire, 2020), Mplus (Muthén and Muthén, 2005) and more recently Apollo (Hess and Palma, 2019) have created a level of accessibility that is crucial for the progress in the science at the foundation of ICLV models, whether it is from the methodological or the application perspective. De facto, the leaps and bounds in understanding human behavior in the travel demand context would have not been possible without these substantial contributions.

Model Applications

Application of the ICLV model to travel behavior and travel demand analysis has focused mostly on the role of attitudes and perceptions in choice behavior, and more marginally on other latent constructs such as norms, beliefs and socialization. The present list does not intend to be exhaustive, but to be indicative of the directions that research prevalently move toward. Most of the interest in the role of attitudes and perceptions is likely driven by the interest in understanding better determinants of choice of sustainable transport solutions. Several studies have investigated the effect of environmental concerns (e.g., Daziano and Bolduc, 2013b; Hess et al., 2013), attitudes toward vehicle features (e.g., design, spaciousness, technology, etc.) attitudes toward vehicle leasing (e.g., Glerum et al., 2013; Kim et al., 2017) and heterogeneity in the population for preferences toward electromobility (Bahamonde-Birke et al., 2017; Kim et al., 2014) on the decision-making process of consumers wanting to buy alternative fuel vehicles. Some studies focused on the propensity toward car sharing being related to environmental concerns and attitudes toward sharing from a general perspective (Efthymiou and Antoniou, 2016; Kim et al., 2017), while other studies have looked at attitudes toward the environment to explain the choice of active travel (Kamargianni and Polydoropoulou, 2013; Maldonado-Hinarejos et al., 2014) or more in general the choice of travel mode (Paulssen et al., 2014; Vij et al., 2013). The versatility of the ICLV model framework has led also to its application to alternative contexts such as security on rail (Daly et al., 2012), car route choices (Prato et al., 2012), freight decision-making (Bergantino et al., 2013), and bicycle route choices (Bhat et al., 2015).

Other studies have investigated latent variables beyond attitudes and perceptions. Personality traits, perceptual factors and travel attitudes were revealed to be latent variables that affect travel mode choice not only directly, but also indirectly via a mediation effect of some latent variables on others. The effect of affective factors and habit on travel mode choice was investigated according to the Theory of Reasoned Action (Tudela et al., 2011), while inertia was measured as a latent habitual effect in travel mode choice (Cherchi et al., 2014). The effect of perceived mobility necessities was considered within the context of departure time choice (Thorhaug et al., 2019), and a hierarchical model was proposed where “values” at the lower level of the psychological construct affected attitudes at the higher level of the same construct, which in turn had an effect on travel mode choices (Paulssen et al., 2014). A similar hierarchical model was used to capture the effect of social interaction on the formation of psychological factors and the decision-making process (Kamargianni and Polydoropoulou, 2013). Even with the significant advancements from the methodological and computational perspectives, and the notable increase in the number of studies in the last decade, the possibilities for the application of the ICLV model to the understanding of travel behavior and the analysis of travel demand are still substantial.

It should be noted that important research directions for the application of ICLV models are the investigation of whether the models introduce benefits when compared with a more traditional choice model without latent variables, especially when considering their effectiveness in drawing policy conclusions (Vij and Walker, 2016), as well as the analysis of the efficiency of estimation methods that would make the model even more accessible than it already is.

Conclusions and Future Prospects

As mentioned in the introduction, while it is obvious that the ICLV model provides substantial contribution to the understanding of human behavior from the behavioral analysis perspective, recent research has posed the question of the actual benefit of using ICLV models from the predictive analysis perspective, and in particular the effectiveness of using these models to draw policies (see, e.g.,

Chorus and Kroesen, 2014; Vij and Walker, 2016). Recent research has also showed that a reduced form model without latent variables fits the choice data at least comparably with respect to the original ICLV model from which it originated, and has concluded that it is important to recognize this truth not to diminish the benefits that are related to the use of the model (Vij and Walker, 2016).

It is however important not to discard the significant advantages of the application of ICLV models to understand human behavior for travel demand analysis, and also not to ignore some necessary considerations for their applications moving forward (Vij and Walker, 2016). Firstly, the comprehension of the behavior benefits substantially from the estimation of ICLV models because it allows for testing complex behavioral theories and imparting meaning to underlying sources of heterogeneity thanks to the identification of relations between variables. Choice models without latent variables would not be able to identify otherwise those relations on the basis of observed characteristics of decision-maker and alternatives. Secondly, the estimation of ICLV models can help correct for omitted variable bias and measurement error when relaxing the assumption of causality that would make the estimates from the ICLV model and its reduced form asymptotically equal. The omitted variable bias and in particular the measurement errors are related to the estimation of models in the early days when psychological and social factors were considered in choice models. Thirdly, the estimation of ICLV models can help the analyst to improve the ability to predict outcomes from the same models because of the reduction of the variance of the model estimates that increases the precision of policy outputs such as marginal rates of substitution. Large errors are in fact associated with the calculation of the latter, especially when computing the ratios between parameters that are distributed across the population. Fourthly, the estimation of ICLV models opens the possibility for the analyst to measure the impact of latent variables on behavior via measures such as demand elasticities and willingness to pay, predict behavioral change as a function of changes in the latent variables over time, and support the design of policies for behavioral change in ways that would simply not possible with choice models without latent variables.

Overall, there are possible guidelines to the process of evaluating that studies bring to the table tangible gains when estimating an ICLV model rather than its reduced form (Vij and Walker, 2016). Relevantly, future research should consider that the ICLV model is a powerful tool in the context of an increasing number of tools available to modelers. As long as analysts are conscientious in terms of the data that they collect, thoughtful in terms of the design of the model framework, and creative in terms of clarifying the value of the ICLV model to practitioners and policy-makers, it can be expected that the model will continue to flourish and eventually provide a substantial contribution also from the predictive perspective.

Introduction

Qualitative research data can be collected through a wide range of methods, such as interviews, focus groups, and participant and non-participant observations. The choice of method/methods are usually not decided until the research perspective and questions are formulated. Sometimes a combination of qualitative and quantitative methods might be used. For example, to discover commuting patterns among people in a city area and their experiences of the same, a quantitative method, like travel survey, might be used together with in-depth interviews and observations. How data is being analyzed varies between disciplines such as anthropology, case studies, ethnography, history, language studies, literature studies, psychology, sociology, social psychology, and a range of hybrid and interdisciplinary research traditions. Hence, how the data is being analyzed depends not only on the theoretical perspective but also on the study contexts and the research question.

This article connects to the previous article on qualitative methods (Chapter XX) and focuses on how qualitative data can be analyzed and then presented. However, it is important to bear in mind that many different methods can be used when analyzing data, some of them this article will only touch upon. For instance, qualitative text analysis, ethnographic fieldwork, news media analysis, image analysis, and analysis of political discourses and social media (for an extensive review see [Silverman, 2004; 2016](#)). Despite this, the general agreement is that analysis is an ongoing, iterative process that begins in the early stages of data collection and continues throughout the study ([Bradley et al., 2007](#)).

Theoretical Perspectives

Quantitative and qualitative studies are different in so far as the first are built on numbers, amounts or quantities; while the latter are built on stories, accounts, or thick descriptions. Inherent in this dichotomy is the view that quantitative studies generally adopt a deductive process (i.e., begins with a theory which is tested), while qualitative studies generally adopt an inductive process (i.e., generate a new theory from data). Although, this distinction is true in general, it does not fully, and accurately, describe the processes adopted by quantitative and qualitative researchers in practice ([Hyde, 2000](#)).

According to literature on qualitative methods (e.g., [Bitektine, 2007; Hyde, 2000](#)), both inductive reasoning and deductive reasoning may support the knowledge production in qualitative research. Inductive reasoning starts with observations of specific instances, seeking to increase and develop the theory through knowledge about the phenomena under investigation. Deductive reasoning starts with a hypothesis and an established theory and seeks to determine if the theory is supported or rejected. Thus, the analysis process of qualitative data can be done either on the basis of the theory guiding the research questions or on the basis of the salient issues that arises in the text itself or on the basis of both approaches. In any case the approach taken will influence the findings and how these are reported ([McGowan et al., 2020](#)).

Types of theories which can be relevant include:

- **Individual theories**—for example, theories of individual development, cognitive behavior, personality, learning, individual perception, and interpersonal interactions
- **Group theories**—for example, theories of family functioning, ageing, gender relations, informal groups, work teams, supervisory and employment relations, and interpersonal networks
- **Organizational theories**—for example, theories of bureaucracies, organizational structure and functions, hierarchy in institutions, and interorganizational relationship
- **Societal theories**—for example, theories on urban development, international behavior, political and cultural institutions, technological development, transport systems, and market functions ([Yin, 2009](#), p. 31)

Some theoretical approaches cut across these theory types, for instance: decision making theory can involve individuals, organizations, and social groups. Another example of cross cutting is the evaluation of public supported programs, such as a national program for traffic safety. Public programs typically include both theories on society and theories on groups or individual behavior.

Transcription

Qualitative researchers who conduct interviews, focus groups, and conversation analysis are often working with transcriptions of audio and/or video recordings. However, there are many variations of how to construct and deal with transcriptions.

By transcription is meant to transfer utterances (by one or more speakers) to written notation, which is performed for the purpose of studying the structure, form, and/or content of the speech or conversation.

In a review of the literature, including 46 journal articles and 30 book chapters or sections from books, [Davidson \(2009\)](#) divides the transcription of qualitative research data into three broad areas: (1) how transcription is defined and understood, (2) how transcription is conducted, and (3) how transcription is reported in research studies.

A general view is that transcription has to be selective, interpretive, and representational. In linguistic anthropology, transcription has been viewed as “cultural practice” or “cultural activity” and transcripts as artifacts that possess “temporal-historical dimensions” ([Duranti, 2007](#), p. 302). Further, transcription is understood to reflect theory and to shape it ([Du Bois, 1991](#)) as researchers “reflexively document and affirm theoretical positions” ([Mischler, 1991](#), p. 271, in [Davidson, 2009](#), p.37) during the process of transcription and analysis.

Researchers make choices, and these are inherently related to the theoretical perspective and how researchers locate themselves and others in the research process. Because it is impossible to record all features of talk and interaction from recordings, all transcripts have to be selective in one way or another. The detail and the scope of the transcript can therefore vary. As [McLellan et al. \(2003\)](#) argue: “at some point, a researcher must also settle on what is transcribed /.../ despite all best intentions, the textual data will never fully encompass all that takes place during an interview” (p. 65).

It may, for example, be limited to certain verbal aspects or include a number of para- or extralinguistic aspects during and between the spoken accounts. According to [Kvale \(2007\)](#), transcripts are artificial constructions from an oral to written mode of communication, and a researcher must make choices in regards to what extent a textual document should also include nonlinguistic observations (e.g., facial expression, body language, and length of pauses) or be transcribed verbatim and identify specific speech patterns, vernacular expressions, intonations, or emotions. [Poland and Pederson \(1998\)](#), for instance, stated that what is not said is just as important as what is said, and thus to grasp the meaning researchers need to include contextual information regarding silence or pauses in conversation (cf. [Goffman, 1981](#)). However, how detailed the transcript should be depends on the aim of the study and the theoretical and methodological framework. One rule of thumb is to make an exact reproduction of what is being communicated and not try to edit the text too early ([McLellan et al., 2003](#)). For instance, correct grammar and mispronunciations.

The practice of transcription might also be divided at several levels. There are both plain and more complicated systems. Some research areas provide detailed information following central notation systems (cf. [Jefferson, 1990/2004](#); [Mondada, 2007](#)) and the emerging field of interaction analysis in mobile settings ([Haddington et al., 2013](#)). Computer technology nowadays makes it possible to both make good recordings and to view recordings as well as developing transcripts on the computer screen using software programs developed specifically for transcription.

Furthermore, language implications might be considered by researchers. Transcriptions that encompass translation from one language to another are especially complex and challenging. It might require the use of interpreters, for example, and transcribers other than the researcher if the researcher is not a native speaker of the language used ([Duranti, 1997](#)). Many researchers use hired professional transcribers, although transcribers often need instruction in relation to the specific purposes of the study and the transcription requirements of it.

According to [Davidson \(2009\)](#) the researchers need to clarify aspects of the transcription for themselves but also to others involved in the research and paid transcribers. Furthermore, the transcription process, which includes selectivity, needs to be articulated in the written reports of the research.

Categorization

The analysis often starts during the transcription procedure when the researcher is carefully listening to audio recordings of interviews or watching video recordings of the interaction between informants. What is regarded as data varies. Some researchers consider research recordings to be “data” and use transcription as summoned representations, where others argue that transcripts are the data.

Qualitative researchers often organize their data in categories, based on concepts, and some form of coding system. Typically, at the first stage of the categorization process the transcripts are analyzed line by line, and pertinent excerpts are given provisional conceptual descriptions (codes). The next stage involves the search for relationships between conceptual labels and to develop categories. At the final stage, categories are integrated and refined.

The following steps represent a systematic approach that allows for open discovery of emergent concepts with a focus on generating taxonomy, themes, or theory ([Bradley et al., 2007](#)):

- Reading for overall understanding.
- Coding, provides the analyst with a formal system to organize the data but also to document additional links within and between concepts described in the data. Codes can be described as tags or labels, which are assigned to whole documents or segments of

documents. According to Bradley et al. (2007) some experts argue that a single researcher conducting all the coding is both sufficient and preferred. However, analysis conducted by one person may not be possible to be repeated by others who have different backgrounds. In this case it would therefore be important to clearly present the researcher's biases and philosophical approaches. In contrast, others recommend that the coding process involve a team of researchers, preferably with differing backgrounds.

- Developing the code structure. How this should be developed depends on if the coding should be inductive or more deductive. See examples here.

Grounded theory encourages the development of codes as purely inductive (Strauss and Corbin, 1998). As more data are reviewed, the specifications of codes are developed and refined to fit the data. To ascertain whether a code is appropriately assigned, the analyst compares text segments to segments that have been previously assigned the same code and decides whether they reflect the same concept. Through this process, the code structure evolves inductively, reflecting "the ground," that is, the experiences of participants.

In contrast, if a deductive approach is used to develop a code structure, the initial step is to use a theory. Although this process started earlier when the interview guide was developed. For instance, if the study is based on the Theory of Planned Behavior, the guide would include questions about: attitudes, norms, and perceived behavioral control (Ajzen, 1991). However, it could be argued that such approach would be rather limited, leaving little room for new discoveries (McGowan et al., 2020). Instead, both an inductive and deductive approach is sometimes used. In this case the structure and the coding are based on the theory, but at the same time nonrelated factors are included.

In order to develop a code structure, five code types have been identified, which can be used to generate taxonomy, themes, and theory: (1) conceptual codes and subcodes identifying key concept domains and essential dimensions of these concepts; (2) relationships codes—links between other concepts; (3) participant perspective codes, which identify, for example, if the participant appears positive, negative, or indifferent about a particular experience or part of an experience; (4) participant characteristic codes; and (5) setting codes.

Interview analysis can be focused on one or more of these code perspectives, depending on the research objectives. In interaction analysis (e.g., focus groups and conversation) the analysts do not talk so much about codes but on building categories from data collections of recurrent and deviant cases—often demonstrated by excerpts from the transcriptions.

Next sections present two examples of how to approach data analysis. The first uses a coding method to extract the interview persons' experiences of a disruptive occasion and the second uses multimodal sequence analysis to identify activities in a situated learning process and the participants' interaction in the specific mobile setting of car driving.

A model of analysis, developed by Graneheim and Lundman (2003) and also practiced by Nyberg et al. (inpress), is based on a matrix organizing the utterances in three levels. The transcribed interviews are read through several times to obtain a sense of the whole and then the transcriptions are extracted into "meaning units," condensed meaning units and codes (see Table 1). In this case the codes represent interviewees experiences of losing their driving license due to visual field injury.

The various codes were in this example compared based on differences and similarities and sorted into tentative categories. Finally, the tentative categories were discussed by a research team and then revised by the main author (Nyberg).

The next example comes from a study called "Driver Training in Practice" (DTriP). The aforesaid analysis was inspired by conversation analysis (CA) (see e.g., Garfinkel, 1967; Goffman, 1981; Sacks, 1992) and so called "tacit knowledge," which is often taken for granted by an experienced driver. Learning to drive is a process of interaction where practical knowledge is communicated from the driver instructor and acted on by the novice trainee driver (cf. Zemel and Koschmann, 2014). Both talk, eye gaze and body movements are important for the practice of learning driving skills. Hence, more than 100 h of driving lessons was recorded in order to monitor what resources the participants use during driving practice (Broth et al., 2019; Levin et al., 2017). The analysis started by thorough listening and watching the video recordings and doing multimodal transcriptions (cf. Mondada, 2007). Recurrent activities, which were of interest due to the research questions were chosen, assigned a unique name, and stored in a data base. These findings constituted collections for further analysis and subcategorization. During the analysis the interaction was analyzed sequence by sequence, and the transcriptions were constructed in increased detail so as to collect as much information as possible; also print screen (photos) from the video recordings or sketches of situations were constructed (see e.g., Broth et al., 2019; Fig. 1).

Validity and Reliability

In quantitative research both validity and reliability are important criterion for describing its quality. Validity is about making sure that the measuring instrument is adapted to what you intend to study and that it reflects real events. Reliability, traditionally, means that a study conducted at a later stage, using the same methods, should arrive at the same results as the previous on (i.e., consistent

Table 1 Excerpt from Nyberg et al. (work in progress)

 04 **&(0.4)&(0.1)+la:stbilen vill köra om dej_z**
 the lorry wants to overtake you
 inst ->+gaze ahead
 tdvr &gz lsvm&gaze ahead

over time). In qualitative research this is not always possible since it is more concerned with exploring “meaning,” in certain contexts, than replication and generalization to a large population (Halliday, 2016; Mason, 2010). Instead, criterions such as credibility, transferability, and trustworthiness are used, and validity and reliability are not regarded as two separate entities (Golafshani, 2003).

Other methods can therefore be used to assess the reliability in qualitative research and provide transparency of the study’s structure. This would mean that the researcher has to justify every move they make (Halliday, 2016). “The general way of approaching the reliability problem is to make as many steps as operational as possible and to conduct research as if someone were always looking over your shoulder” (Yin, 2009, p. 38).

The question is also if the study has been analyzed in a detached way or if the results partly reflects the researchers preconceived ideas. The pre-understandings and conditions need to be clear (Silverman, 2004). According to Thomas (2003) the trustworthiness of findings can be assessed by a range of techniques, such as: (1) independent replication of the research, (2) comparison with findings from previous research, (3) triangulation within a project, (4) feedback from participants in the research (so-called “member checks”), and (5) feedback from users of the research findings.

The accuracy of the interpretation of data from an interview study can also be checked using so-called “member checks,” which means that participants in the study are able to review, comment, and/or correct the material: (1) review a transcript of their own interview, (2) a copy of preliminary findings, and (3) a draft copy of a research manuscript. Member checks can be useful for obtaining participant approval when using quotations and where anonymity cannot be guaranteed (Thomas, 2017).

Publishing

Qualitative studies usually result in a large amount of data, which means that even at this stage some form of selection is needed. Thus, the writing process should be considered a stage in the analysis process.

Publishing in high impact scientific journals versus popular science magazines or stakeholder reports are quite different (see Table 2) but also show some similarities. In all cases the message needs to be clear and the presentations be adapted to the readers’

Table 2 Audiences and their expectations

Audience	Expectations
Academic colleagues	Theoretical, factual, or methodological insights; scientific dialogue
Policy makers	Practical information and knowledge development relevant to policy issues; problem solving
Practitioners	A theoretical framework for understanding clients/customers better; factual information; practical suggestions for better procedures; reform of existing practices
The general public	New facts; ideas for reform of current practices or policies; reflecting their everyday life and confirmations that others share their own experience of particular problems; improvements; guidelines for how to manage better or get better service from practitioners or institutions

Source: Adapted from Silverman, 2001. *Interpreting Qualitative Data. Methods for Analysing Talk, Text and Interaction*. Sage, London, p. 267.

knowledge and interest. Clark and Thompson (2016, p. 2) point out that the writer should nail the key message: strong, clear, and concise about what the research found and why this is important. With too many messages, the main points of the paper are lost. If there are no clear messages, the readers are wondering “what’s the point?”

Most qualitative, inductive studies report between three and eight main categories and often pick out exceptions to illustrate these findings in their publications. Inexperienced researchers often try to report 10 or more major categories. This indicates that they have probably not finished the process of combining the smaller categories into larger categories or that they have not made the crucial decisions about which categories are the most important (Thomas, 2003).

Quotes from transcriptions are used as verifications of analysis results and can be considered as part of the validation procedure in qualitative research. Quotes typically illustrate the results and verify the story when writing and publishing. Quotes and excerpts for publications should be chosen to exemplify recurrent and/or specific findings or deviant cases, which are discussed in the text. Note that the academic journals often need concise messages about the research findings and convinces why it is important—a large number of quotes without scientific discourse does not serve these purposes.

Caulley (2008) argues that qualitative researchers should be more generous in using concrete details from fieldnotes or notes from research diaries. It is important for the researcher to be a careful observer of details. However, it is also crucial to handle data carefully with respect to interviewees and participants’ integrity who may not have given their consent to become identifiable in either scientific reports or popular science media.

Note that researchers usually select journals only after most, or all, of the manuscripts have been written, which is a mistake. The advice from editors is to view the work more in terms of how it fits with specific journals and use this as a help when writing the paper. Editors usually have a vision of who are their readers and intended readers and the kinds of articles they want in their journal. “Try to get a better sense of this vision by taking opportunities to communicate with editors at conferences, on social media, and via e-mail” (Clark and Thompson, 2016, p. 2–3).

Summary and Conclusions

In transportation research, various analysis methods are practiced to understand complexity of human behavior but also their needs and motivations. This article discusses analysis of qualitative data, using examples from audio recorded interviews and video recordings of sequential interaction. Qualitative analysis is built on stories, accounts, or “thick” descriptions. The approach can be described as inductive (i.e., starts with an observation and ends with a theory) although a deductive approach can also be used (i.e., starts with a theory, which is tested). How the data is being analyzed depends on the theoretical perspective but also on the study contexts and the research question.

The analysis in qualitative research often starts during the transcription procedure when the researcher is listening to audio recordings of interviews or watching video recordings of the interaction between informants. Invariably this results in a large amount of information and all transcripts have to be selective in one way or another. The next step is to organize the data in categories, based on concepts, and in some coding systems, which help to organize data in collections or clusters. One conclusion is that coding systems can be either theory or data driven. The article also discusses the assessment of validity and reliability in qualitative research, which is different from quantitative studies. In qualitative research they are not regarded as two separate entities and criterions such as: credibility, transferability, and trustworthiness are used instead.

The selective process finishes when writing the results, and they should be considered a stage in the analysis process. Quotes from transcriptions are used as verifications of analysis and can be considered as part of the validation procedure in qualitative research. They typically illustrate the results and verify the story when writing and publishing quotes and excerpts, which should be chosen to exemplify recurrent and/or specific findings or deviant cases, which are discussed in the text.

Driver Distraction and Inattention

There is converging evidence, reviewed in this chapter, that driver distraction is a significant road safety problem. Driver distraction is one mechanism of driver inattention. [Regan et al. \(2011\)](#) conceptualized this relationship by developing a taxonomy of driver attention using previous classifications of attentional failures identified as having contributed to crashes in in-depth crash studies (e.g., [Hoel et al., 2010](#); [Treat 1980](#); [Van Elslande and Fouquet 2007](#); [Wallén Warner et al., 2008](#)). [Regan et al. \(2011\)](#) defined driver inattention as “insufficient or no attention to activities critical for safe driving” (p. 1776) and proposed that driver inattention is induced by five attentional mechanisms (identified in [Fig. 1](#)), one of which they labeled “Driver Diverted Attention”; which is synonymous with driver distraction (see [Fig. 1](#)). [Regan et al. \(2011\)](#) defined Driver Diverted Attention (i.e., driver distraction) as “the diversion of attention away from activities critical for safe driving toward a competing activity, which may result in insufficient or no attention to activities critical for safe driving” (p. 1776). This definition was grounded on an earlier definition formulated by [Lee et al. \(2009, p. 34\)](#) that was subsequently endorsed by an international group of experts convened by the International Organisation for Standardization (ISO): “Driver distraction is the diversion of attention away from activities critical for safe driving toward a competing activity”.

Types of Distractions and Triggered Responses

Many different sources of distraction have been identified in crash and naturalistic driving studies, and these have been categorized as follows ([Regan and Hallett, 2011](#)): objects (e.g., mobile phone, advertising billboard); events (e.g., crash scene, lightning); passengers (e.g., child, adult); other road users (e.g., cyclists, pedestrians, other vehicles); animals (e.g., dog); and internal stimuli (e.g., that trigger day dreams and thoughts). A source of distraction has certain “modal properties” (e.g., visual, auditory; [Hallett et al., 2011](#)) which, along with other properties, may trigger a diversion of attention away from activities critical for safe driving.

Different “types” of distraction can be classified according to the sensory modality through the diversion of attention is triggered. [Regan and Hallett \(2011\)](#) conceptualized six types of distraction, distinguished by the diversion of attention towards things that:

- we see (“visual distraction”)
- we hear (“auditory distraction”)
- we smell (“olfactory distraction”)
- we taste (“gustatory distraction”; e.g., the taste of a rotten piece of fruit), and
- we feel (tactile distraction; e.g., the feel of a large spider crawling on one’s leg).

The actions that a driver may perform while engaged in a competing activity are potentially enormous (e.g., looking, reaching, touching, etc.). However, the behavioral effects triggered by these driver actions are finite in number. [Hallett et al. \(2011\)](#) have referred to these behavioral effects as “triggered responses”, and have characterized them (for distracted drivers) as follows:

- Eyes off the Road – driver takes eyes off activities critical for safe driving
- Mind off the road – driver takes mind off activities critical for safe driving

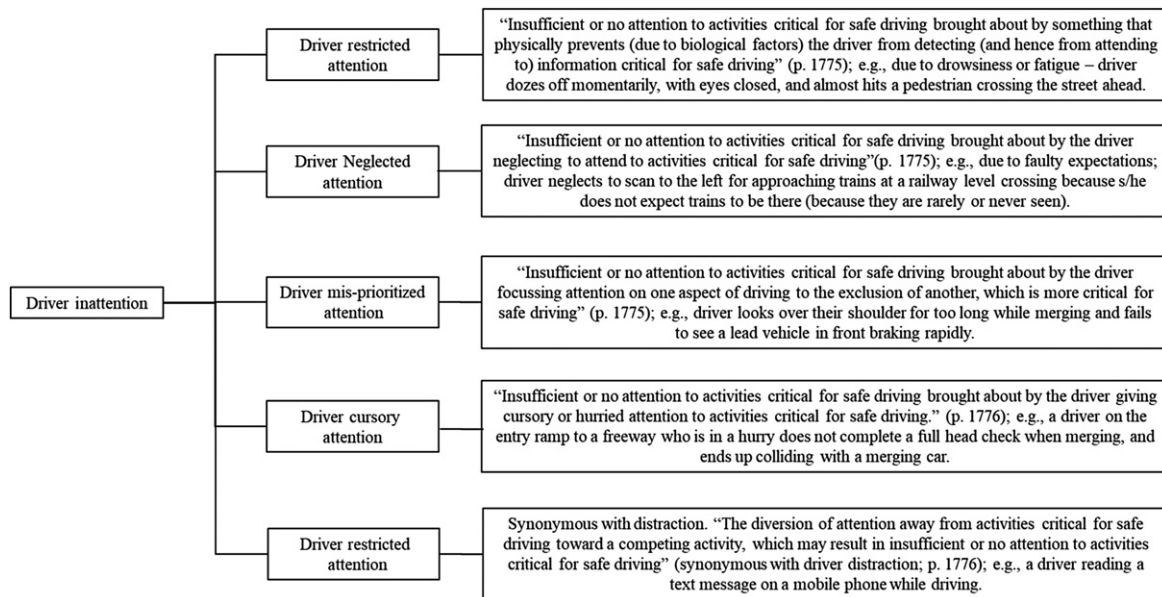

Figure 1 Mechanisms of Driver Inattention Source: [Regan et al. \(2011\)](#).

- Ears off the road – driver takes ears off activities critical for safe driving (as a result of having one's mind off the road), and
- Hands or feet off (vehicle) controls – driver takes hands and/or feet off activities critical for safe driving.

Different competing tasks induce distinctive triggered responses, often in combination. For example, looking at an advertising sign will take a driver's "Eyes off the Road" and their "Mind off the road" when thinking about the message(s) it conveys.

Impact on Driving Performance

The triggered responses induced by the different types of distraction have been found to interfere with, and degrade, driving performance in various ways (see [Bayly et al., 2008](#); [Bruyas, 2017](#); [Horberry and Edquist, 2009](#); [Oviedo-Trespalcacios et al., 2016](#)).

Competing activities that mainly take drivers' eyes off the road have been found to affect some specific aspects of driving performance:

- the selection of information (e.g., failing to detect relevant roadway information; spatially concentrated gaze on the forward road centre when the driver's eyes are returned to the forward roadway);
- information processing (e.g., longer reaction times to braking lead vehicles and roadway warnings; "change blindness" that inhibits the detection of changes in the road scene); and
- vehicle control (e.g., degraded lane keeping performance; reduced speed; increased following distance).

Competing activities that mainly take a driver's *mind* off the road are also known to affect specific aspects of driving performance:

- selection of information: reduced checking of speedometer and rear-view mirrors, and less attention to hazards in the periphery due to spatially concentrated gaze on the forward road centre;
- information processing: inattention blindness, missing red lights, and the inability to remember some things that have been seen during a drive;
- vehicle control: more hard braking, more navigation errors, changes in lane keeping performance, changes in following distances and speed, and fewer lane changes; and
- more traffic rule violations: speeding, red light running, crossing solid lines.

Factors Moderating Driver Distraction

The same competing activity (e.g., typing a text message) can have different effects on activities critical for safe driving depending on a range of moderating factors. These include ([Oviedo-Trespalcacios et al., 2019a](#); [Young et al., 2009](#)):

- Driver characteristics: such as age, gender, driving experience, driver state (e.g., drowsy, drunk, angry), familiarity with and amount of practise with the competing task, and personality (e.g., the propensity to take risks) ([Huth and Brusque, 2014](#); [Oviedo-Trespalcacios et al., 2020a](#); [Young et al., 2009](#)).

- Driving task demand: characteristics of the driving task itself, such as traffic conditions, weather conditions, road conditions/design, the number and type of vehicle occupants, the ergonomic quality of vehicle cockpit design, and vehicle speed (Li et al., 2020; Onate-Vega et al., 2020; Oviedo-Trespalcacios et al., 2017, 2020a; Young et al., 2009).
- Secondary task demand: competing (secondary) tasks may degrade driver performance depending on (1) how similar the task is to driving sub-tasks (e.g., whether it requires visual and/or manual control actions similar to those required for driving), (2) its complexity, (3) whether or not it can be ignored, (4) how predictable it is, (5) how easily it can be adjusted, (6) how easy it is for the task to be interrupted and resumed, and (7) how long it takes to perform the task (Oviedo-Trespalcacios et al., 2020a; Regan et al., 2011; Young et al., 2009).
- Self-regulation: the ability of a driver to regulate behavior in the face of, or in anticipation of, a competing activity in order to compensate for its potentially adverse effects (Oviedo-Trespalcacios et al., 2019a; Young et al., 2009). This can occur at different levels of driving control: strategic (e.g., turning on mobile phone applications that prevent mobile phone use while driving); tactical (e.g., limiting or ceasing phone use in complex traffic conditions); and operational (e.g., compensating for increased demands by increasing headway distance or reducing speed) (Chen et al., 2020; Li et al., 2019; Oviedo-Trespalcacios, 2019a; Saifuzzaman et al., 2015).

Evidence Implicating Distraction as a Traffic Safety Problem

Both crash archives and crash risk studies have associated distraction with increased risk of road crashes.

Crash studies using official archives are frequently found in the literature. A review of studies using police archives from New Zealand and the United States found that 10%–12% of police-reported crashes were linked to driver distraction (Gordon, 2009). A more recent investigation in the United States using the Fatal Accident Reporting System (FARS) database reported that 7.7% of all fatal crashes involved distraction (Qin et al., 2019). In Australia, Beanland et al. (2013) found that 13.9% of casualty crashes were associated with in-vehicle sources of distraction, such as mobile phones or animals/insects in the vehicle. In Norway, Sundfør et al. (2019) found that 2%–4% of all fatal crashes involved mobile phone use while driving, whilst interaction with other sources of in-vehicle distraction, such as GPS, laptop or tablet computers, video cameras, backing cameras, and passengers, contributed to 8% of all fatal crashes. Eby and Kostyniuk (2003) determined that single-vehicle-run-off-the-road crashes and rear-end crashes are the most common types of crash associated with driver distraction.

Crash studies using archival data lack behavioral detail around the circumstances of driver distraction: many crashes considered to involve distraction in the United States, for example, are listed as “distraction/inattention details unknown” in official crash data (NHTSA 2016). To overcome this limitation, crash risk studies have been undertaken that produce this behavioral detail and estimate changes in crash risk associated with distracted driving.

Crash risk studies provide information about the increased driving risk posed by driver involvement in a distraction-related activity over and above that of the risk posed by “normal” driving. Naturalistic driving studies (NDS), where driver and vehicle behavior are recorded using video, accelerometers and other unobtrusive instrumentation, for long periods of time, have provided crash risk estimates for a wide range of distracting activities. The *Strategic Highway Research Program (SHRP 2)* naturalistic driving study in the United States is the largest and most comprehensive such study in the world, having involved nearly 3500 drivers for three years. From the SHRP 2 study, Dingus et al. (2016) reported that observable distractions, overall, increased the odds of having a crash by a factor of 2.0.

Another comprehensive naturalistic driving study in the United States was conducted by Fitch et al., (2013) to investigate changes in crash risk due to handheld and hands-free phone use among 204 drivers during a period of 4 weeks. Fitch et al. (2013) found handheld mobile phone use, overall, to increase the odds of having a crash by a factor of 1.39, while Dingus et al. (2016) reported SHRP 2 data confirming that interaction with a handheld mobile phone, overall, increased the odds of a crash by a factor of 3.6.

Table 1 summarizes the results from these key studies and identifies increases in risk associated with driver engagement in a range of other distracting activities. Noteworthy are increases in risk associated with talking on a handheld phone, ranging from 0.79 (Fitch, 2013) to 2.2 (Dingus et al., 2016). Recently, Young (2017) recalculated the odds ratio of handheld mobile phone conversations using the SHRP 2 data after controlling for selection and confounding bias, which have been noted by others as issues in some of these studies (see Wijayaratna et al., 2019). This resulted in an odds ratio of between 0.94 and 0.92. Neither value is significantly different from 1, implying that there is no increase in risk associated with talking on a handheld mobile phone. These values are similar to findings reported in previous naturalistic studies (Fitch et al., 2013).

Distraction can also derive from driver exposure to sources external to the vehicle. Generally, these have not received the same level of attention in the published research as in-vehicle distractions. Around 30% of distraction-related crashes derive from driver engagement with sources outside the vehicle. These include animals, architecture, advertising signage, construction zones/equipment, crash scenes, incidents (e.g., road rage), insects, landmarks, road signs, road users, scenery, other vehicles and weather (e.g., lightning) (Gordon, 2009).

In a Systematic Review conducted by Oviedo-Trespalcacios et al. (2019b), there was a trend in the literature of reporting an increased crash risk associated with driver interaction with digital billboards. It is known from the work of Dingus et al. (2016) that an extended eye glance duration to an external object increases the odds of having a crash by a factor of 7.1 (OR). Roadside advertising signs are designed deliberately to attract and maintain driver attention to information that is irrelevant to driving.

Table 1 Summary of crash risk findings from naturalistic driving studies

<i>Study</i>	<i>Observed distraction</i>	<i>Odds ratio (95% CI)</i>
Fitch et al. (2013)	Mobile phone visual-manual task (i.e., text messaging/browsing, locate/answer, dial, push to begin/end use, and end handheld phone use)	1.73 (1.1–2.7) ^a
	Mobile phone handheld talk	0.79 (0.43–1.44)
	Mobile phone portable hands-free talk	0.73 (0.36–1.47)
	Mobile phone integrated hands-free talk	0.73 (0.36–1.47)
Dingus et al. (2016)	Observable distraction (overall)	2.0 (1.8–2.4) ^a
	Total mobile phone handheld	3.6 (2.9–4.5) ^a
	Mobile phone handheld talk	2.2 (1.6–3.1) ^a
	Mobile phone browse	2.7 (1.5–5.1) ^a
	Mobile phone handheld dial (a number)	12.2 (5.6–26.4) ^a
	Mobile phone handheld text	6.1 (4.5–8.2) ^a
	Mobile phone handheld browse	2.7 (1.5–5.1) ^a
	In-vehicle information systems	4.6 (2.9–7.4) ^a
	Extended eye glance to an external object	7.1 (4.8–10.4) ^a
	Reading and writing (including with tablets)	9.9 (3.6–26.9) ^a
	Personal hygiene activities	1.4 (0.8–2.5) ^a
	Eating	1.8 (1.1–2.9) ^a
	Reaching for objects inside the vehicle (excluding mobile phones)	9.1 (6.5–12.6) ^a
Young (2017)	Mobile phone handheld talk	0.94 (0.30–2.3) or 0.92 (0.45–1.7)

^aSignificantly increase driving risk

Prevention and Management of Distracted Driving

Traditionally, the responsibility for managing distraction has been on the driver. This view implies that when engaging in distraction drivers are solely to blame for any adverse outcomes. Generally, this “victim blaming” approach has, to date, been the status quo of distraction prevention. However, safety experts concur that this approach is unsuitable for dealing with distracted driving (or any other risky behavior; Tingvall and Haworth 1999; Tingvall et al., 2009; Young and Salmon, 2015). Drivers tend to be, and will continue to be, distracted due to a number of factors that are often difficult to control. For example, recent research has shown that problematic mobile phone use has characteristics that resemble addiction (Oviedo-Trespalcacios et al., 2019c). The connection between problematic phone use and distracted driving suggests that the involvement of wider mental health stakeholders may be needed to prevent mobile phone use while driving.

Given that current prevention strategies mainly targeting the driver (i.e., their motivation and beliefs about the risks of engaging with secondary tasks) have shown limited effectiveness, there has been a move recently towards considering the role of all stakeholders in society with responsibilities for the management of driver distraction. The premise is that distracted driving is a product of wider systems factors that are imposed on drivers (Parnell et al., 2016). Nowadays, some groups of stakeholders, directly linked with distracted driving, have not assumed their responsibilities (Oviedo-Trespalcacios et al., 2019c; Parnell et al., 2017; Young and Salmon 2015). An example is the often-complacent role of the creators of mobile phone applications used by drivers, who have the technology available to prevent it (Galitz, 2017). There is no doubt that effective prevention of distraction lies in the active participation of a wider group of stakeholders in society that hold responsibility over distraction. Guaranteeing the active participation and cooperation of major stakeholders such as government, industry, drivers, technology developers etc. in the prevention of distraction is a key task for road safety practitioners and policymakers.

Countermeasures for Distracted Driving

Many countermeasures have been developed in an attempt to prevent and mitigate distracted driving. Unfortunately, very few have been evaluated to establish their effectiveness. Table 2 includes countermeasures supported by empirical research, with a focus on those which have reduced the occurrence or impact of distracted driving. The countermeasures are organized following the hierarchy of controls for the management of risks. The most effective are those that focus on “Elimination” - the elimination of the risk - and the least effective are those that focus on the provision of Personal Protective Equipment (PPE) to protect the body from injury.

Looking to the Future

Distraction is likely to continue to be a road safety problem, even as vehicles become increasingly automated. For partially automated vehicles, there is currently no evidence that these reduce distraction. On the contrary, partial automation has been

Table 2 Countermeasures for distracted driving

<i>Types of countermeasures</i>	<i>Definition</i>	<i>Countermeasures</i>
Elimination	Involves complete physical removal of the hazard and risk it creates. This might be difficult to implement in certain circumstances such as distracted driving from mobile phone use, as drivers have reported difficulties separating from their phones (George et al., 2018). Nonetheless, elimination should always be considered and implemented before the other methods.	Fully Automated Vehicles (FAV) SAE Level 4-5: Vehicles that do not require a human operator to control or monitor the vehicle. Therefore, it is anticipated that as the driver will not have responsibility to control or monitor the vehicle distraction will not play a significant role. Projected benefits of these vehicles might only be observed in 25-30 years (Clark et al., 2016; Dia 2015).
Substitution	Involves substituting the risks with lesser hazardous practice or material. It must be implemented in the very early phases of development.	Workload managers: Driver-support systems that present driving and non-driving related information in such a way that road-users are not distracted. The technology could reduce distraction from driver-assistance systems (driving-related information; Teh et al., 2018), but the effectiveness of managing non-driving related information is unknown.
Engineering Controls	Involves controlling identified hazards through the modification or addition of physical safety features to equipment or machinery.	Road design: PIARC (2016) recommends using road engineering treatments such as concrete or steel side barriers, wire rope side and median barriers, speed humps, rough shoulders, variable speed signs, etc. to mitigate driver distraction. SAE Level 3 Partial Driving Automation Vehicle (also known as autopilot): The vehicle can perform key control tasks, but drivers are supposed to maintain steering and take over control of the vehicle at all times. Research suggests that drivers are likely to engage in distraction while driving partially automated vehicles (Lin et al., 2018), potentially resulting in road crashes. Advanced Driver-Assistance Systems (ADAS; available in SAE Level 1-2 vehicles): ADAS support drivers with some automation features (e.g., cruise control, lane centering, etc.) and can also provide warnings for upcoming collisions (e.g., forward collision warning, etc.), thus preventing and mitigating some distraction-related crashes. Evidence suggests that ADAS could, to the contrary, increase distraction through poorly designed warnings/alarms (Biondi et al., 2014; Thompson et al., 2018), and in-vehicle information systems (IVIS) can elicit means for drivers to engage in non-driving tasks (Oviedo-Trespalcacios et al., 2019d). Blocking technology: Includes mobile phone applications and hardware which seek to block mobile phone use while driving. This technology is effective in reducing mobile phone use while driving (Oviedo-Trespalcacios et al., 2020b; Albert and Lotan, 2019; Ponte et al., 2016), but acceptance is low among drivers (Oviedo-Trespalcacios et al., 2019e, 2020c; Ponte et al., 2016; Reagan and Cicchino, 2020). Feedback systems: Delivers information to drivers on their performance. Research has found feedback systems that consider parental norms and real-time feedback are associated with a smaller duration of off-road glances (Merrikhpour and Donmez, 2017). Legislation: Legislation banning the use of mobile phone devices whilst driving. Very few such bans have been evaluated, and there are mixed reports about the effectiveness of bans across jurisdictions. Police enforcement: Police operations to increase compliance of legislation banning different forms of mobile phone use while driving. Research has shown that police officers are unable to correctly enforce legislation in many circumstances due to lack of resources, poor visibility inside vehicle, etc. (Nevin et al., 2017; Rudisill et al., 2019). Driving for work procedures/ policies: Implementation of Workplace Health and Safety (WH&S) organizational
Administrative Controls	Involves changing the way individuals work through limiting exposure to a hazard. This method is not always reliable or effective as it is prone to variability of human performance.	

(continued)

Table 2 Countermeasures for distracted driving (*cont.*)

<i>Types of countermeasures</i>	<i>Definition</i>	<i>Countermeasures</i>
Personal Protective Equipment (PPE)	Involves protecting the body from injury (e.g., gloves, safety glasses, earplugs). PPE is deemed to be the least effective method as it does not eliminate the hazard. Regarding distracted driving, PPE corresponds to post-crash safety measures such as seatbelts, airbags and other passive safety elements to minimize the impact of a crash.	procedures/policies to reduce distracted driving and enhance safety of drivers. Research has found truck and bus drivers working for organizations that enforced texting bans have lower texting and driving prevalence in comparison to companies without bans (Hickman et al., 2010). Educational programs: These programs include strategies on how to reduce mobile phone use while driving. Some examples include “<i>It Can Wait</i>”, “<i>Just Drive—Take Action Against Distraction</i>”, and “<i>Steering Teens Safe</i>”. The programs were found to be effective to a certain extent. Training programs: The “<i>Forward Concentration and Attention Learning (FOCAL)</i>” research-led training program consists of three stages: pre-test, training, and post-test. Drivers who received the FOCAL training engaged in fewer in-vehicle glances longer than 2 s by roughly 25 percentage points when compared to the placebo group (Unverricht et al., 2019). Seatbelts, Vehicle Design, and Emergency Care: Prior research has found these measures to reduce the severity of crashes (Bhattacharyya and Layton, 1979).

shown to create distraction due to decreased engagement with the driving task (Cunningham and Regan 2018b; Kanaan et al., 2020; Regan et al., 2020). A study in China with Tesla drivers, for example, found that drivers often engage in distracting activities while using the autopilot system (Lin et al., 2018). Similar findings have been reported in the U.S., where drivers of vehicles with ADAS, such as adaptive cruise control, report engaging more in mobile phone use and texting (Dunn et al., 2019). Matthews et al., (2019) showed that autopilot systems elicit subjective symptoms of fatigue and loss of alertness that last even after the autopilot system has been deactivated. Likewise, as vehicles become more automated, the human-machine interfaces for the technologies that automate driving could themselves become sources of distraction. Evidence already exists showing that automation actions and alerts that are unexpected, because of a lack of training, lack of situational awareness, or some other mechanism, may create “automation surprises” (Hollnagel and Woods, 2005); and, in doing so, distract drivers. An understanding of, and development of countermeasures for, driver distraction at all levels of automation is a future concern for traffic safety.

Concluding Comments

In this chapter we have introduced the reader to the field of driver distraction: its definition and mechanisms, its impact on traffic safety, prevention approaches, and countermeasures. The focus of the chapter has been on driver distraction, although we acknowledge that there are other road users vulnerable to the effects of distraction, including riders and pedestrians. Greater coordination between stakeholders with responsibility for preventing and managing driver distraction, and a greater emphasis on the evaluation of distraction prevention and mitigation countermeasures, will be important overarching strategies in managing distraction into the future. As appropriately concluded by the European Commission (2018), countermeasures to distraction should be derived from the best available and reliable scientific knowledge of the underlying mechanisms of distraction, the prevalence of different distractive activities and the risks associated with these activities.

Acknowledgment

Dr Oscar Oviedo-Trespalacios’ contribution to this chapter was partially funded by an Australian Research Council Discovery Early Career Researcher Award [DE200101079].

General Anger and Aggression

The concepts of anger and aggression are two related but different constructs. The American Psychologists Association defines anger as “an emotion characterized by tension and hostility arising from frustration, real or imagined injury by another, or perceived injustice” (APA, 2020a). Aggression can be defined as “behavior aimed at harming others physically or psychologically” (APA 2020b). Thus, although strongly related, anger describes the emotion experienced, while aggression relates to the expression of anger in behavioral terms. The concept of driving anger originated in a clinical setting, where psychologists attempted to understand and treating problem anger in a driving context (Deffenbacher et al., 1986). These clinical findings spawned a program of research to explore whether the propensity to experience anger in the driving setting was a specific type of trait anger, which situations cause drivers to become angry, what drivers do when angry and the thoughts angry drivers have (Deffenbacher et al., 1994, 2002, 2003). Deffenbacher et al. (1994) defined driving anger as a situation specific form of trait anger, with research reporting low to moderate correlations with general trait anger (e.g., Deffenbacher et al., 1994). However, one of the most consistent findings has been that those higher in trait driving anger are more likely to become aggressive while driving (Berdoulat et al., 2013; Blankenship et al., 2013; Dahlen and White, 2006; Iversen and Rundmo, 2002; Lajunen et al., 1998; Lajunen and Parker, 2001; Li et al., 2014; Millar, 2007; Suhr and Nesbit, 2013).

Aggressive Driving

The term aggressive driving is used differently in the driving context to the definitions used by the APA for general aggression. For example, Lajunen and Parker (2001) distinguish between “aggressive driving” and “aggressive drivers” with the main difference being the ability to understand the intent of aggressive drivers; but not aggressive driving. The two most used definitions for aggressive driving reflect this distinction. The American Automobile Association (AAA, 2014) defines aggressive driving as: “Any unsafe driving behavior, performed deliberately and with ill intention or disregard for safety” (AAA Foundation for Traffic Safety, 2016); thus, requiring an understanding of motivations behind the behaviors. In contrast, the National Highway Traffic Safety Administration (NHTSA) define aggressive driving as “the operation of a motor vehicle that endangers or is likely to endanger persons or property” (Stuster, 2004). This definition removes the subjective element and is more suitable for enforcement purposes.

Behaviors that are considered aggressive, within these two definitions, include:

- Driving in excess of the speed limit (speeding);
- Following another driver too closely (tailgating);
- Dangerous overtaking;
- Weaving in and out of traffic;
- Preventing other drivers from merging or passing;

Figure 1 Types of aggressive driving and general prevalence. Source: NB Prevalence taken from AAA Foundation for Traffic Safety (2016), Stephens and Fitzharris (2019).

However, aggressive acts can range on a continuum from seemingly benign actions (such as mild gesticulating or swearing under one's breath) to extreme acts of aggression (see Fig. 1). Neither of these is considered within the above definitions, yet it is often these ends of the spectrum that drivers and researchers refer to as aggressive driving. Thus, a paradox in this field is that while most drivers can easily recount a time when another driver has been aggressive towards them, the definition of aggressive driving is not consistent across drivers, researchers or road safety agencies.

Road Rage and Aggressive Driving

A further inconsistency in aggressive driving research is the use of the term road rage. A number of researchers use road rage synonymously with aggressive driving, referring to minor acts of horn honking, or swearing as road rage. However, this oversimplifies a complex problem and can lead to a disregard of aggression as a genuine road safety concern (Elliott, 1999).

The NHTSA defines road rage separately as a criminal offense, while aggressive driving is a traffic violation (Stuster, 2004). This definition recognizes the extreme and violent nature of road rage, which could be deemed assault. As can be seen in Fig. 1, we propose that aggressive behaviors should be considered across two broad categories and road rage as an extreme separate construct. Thus, we suggest aggressive driving may include:

- minor aggressive behaviors, which are not enforceable and may constitute culturally common behaviors, such as swearing or gesticulating, horn honking, or flashing lights;
- enforceable aggressive driving behaviors that, as per the NHTSA definition, includes the use of a vehicle that endangers or is likely to endanger other road users and, as per the AAA definition, may be the results of ill intention or a disregard for safety.

These two categories may both be considered within the aggressive driving framework, particularly for research purposes. In addition, we propose that, as per the NHTSA definition, road rage can be defined as:

- Extreme acts of violence punishable as a criminal offense, which includes physical assault.

Road rage is, therefore, not considered to be aggressive driving and will not be included in the following literature review.

The Prevalence of Aggressive Driving

The inconsistent definitions for aggressive driving make it hard to understand its prevalence. In addition, as certain proxy behaviors (i.e., speeding) are considered to be road safety issues in their own right, the prevalence of aggressive driving may be understated. Nonetheless, research consistently shows that most drivers will experience aggression from other drivers at some point, and that the majority of drivers will also act aggressively themselves (Europe, 2003).

The largest global survey on aggressive driving was conducted in 2003 and included over 13,000 drivers from 23 countries (Europe, 2003). These included countries in Europe, the UK, the USA, South America, Russia, and Australasia. The results showed that, globally, it was common to receive aggression from others, with between 26% and 66% of respondents in each country reporting being the victim of aggression in the previous year. The types of aggression surveyed included minor aggressive acts, such as verbal abuse, gesticulating and flashing lights—which were the most frequently reported—to enforceable aggression, such as being pursued by another driver, which was considerably less frequent. Physical attacks were the least common with 1%–10% of those

who had reported receiving aggression, reporting it in this form. Interestingly, the types of aggression most frequently received differed across countries, suggesting a cultural element to aggressive driving and/or the perception of others' behavior as aggressive.

Perpetrating aggressive driving behavior is as common, if not more common as receiving it. In the global study, between 36% and 69% of drivers had been aggressive at least once in the previous year (Europe, 2003). More recent national studies have shown that most drivers will be aggressive at least once in a 12-month period. Data from the USA and Australia show that over 80% of drivers reported aggression (AAA Foundation for Traffic Safety, 2016; Stephens and Fitzharris, 2019), which included behaviors ranging from minor aggression to enforceable aggressive behaviors (see Fig. 1).

As would be expected, when considered across specific behaviors, the prevalence of aggressive acts decreases as the severity of the act increases. For example, Stephens and Fitzharris (2019) reported that 71% of Australian drivers sound their horns when angry; while more serious aggression such as tailgating were reported by 45% of drivers, and pursuing another driver when angry reported by 10% of drivers. Likewise, 51% of drivers in the USA reported tailgating, with 12% deliberately cutting off another vehicle and an alarming 4% exiting the vehicle to confront another driver (or to engage in road rage) (AAA Foundation for Traffic Safety, 2016). Interestingly, in the USA, sounding the horn was reported by 45% of the sample, indicating less drivers engaged in horn honking than tailgating or yelling at another driver (47%). This again highlights a culturally specific element of aggression and the repertoire of behaviors that are commonly used to express anger.

While concerning, these figures do not represent the frequency with which drivers engage in the behaviors every time they drive. Most drivers do not "always" act aggressively. For example, in a Canadian report of behaviors exhibited "often" while driving, 20% of drivers swore, while only 6% used their horn aggressively (Vanlaar et al., 2007). Thus, there is a notable decrease in prevalence when considering how often each driver engages in the behavior, rather than just whether they engage in the behavior or not.

Overall, the research shows that aggression remains common on the roads. However, in which aggression is displayed and the frequency of this will differ across driving cultures. Minor acts of aggression are more common than more extreme aggression, although a notable proportion of drivers still engage in dangerous aggression, just relatively infrequently.

Is Aggressive Driving Increasing?

While many drivers perceive that aggression is increasing (AAA Foundation for Traffic Safety, 2016; Vanlaar et al., 2008), there is limited evidence to suggest this is the case. As reported above, the general population prevalence of aggressive acts are similar for studies published in the 2000s (e.g., Europe, 2003) and more recent reports (e.g., AAA Foundation for Traffic Safety, 2016; Stephens and Fitzharris, 2019). Vanlaar et al. (2007) compared self-reported frequencies of aggression between different samples of drivers in Canada taken in 2001 and 2006 and showed no significant differences across the two time points. This was evident across minor aggressions, such as swearing, sounding the horn and gesticulating, as well as for enforceable aggression, such as speeding through red lights.

Møller and Haustein (2018) found slight increases in aggression, when comparing self-reports from independent samples of drivers in Denmark measured in 2005 and 2016. A higher percentage of drivers in the 2016 sample, compared to the 2005 sample, reported having yelled at another road user (19% cf 12%), gesticulating (13% cf 10%) and hitting another vehicle (2% cf <1%). However, there were no differences in the percentages of drivers reporting hitting other road users or threatening other road users. The main differences between the studies by Møller and Haustein (2018) and Vanlaar et al. (2007) was the frequency response rate, with Møller and Haustein (2018) comparing drivers who had engaged in each behavior over the previous 12 months against those who had not. In comparison, Vanlaar et al. (2007) compared the percentage of drivers who reported engaging in the behaviors often in the previous 12 months. Thus, there is no evidence to suggest that aggressive drivers increase the frequency of these behaviors over time, and only limited evidence to suggest that more drivers are adopting certain aggressive behaviors.

Aggressive Driving, Crash, and Injury Risk

Despite the inconsistency in defining aggression, and in understanding its prevalence, aggressive driving is consistently associated with crash risk. This finding is robust across different data collection methods.

Survey research has shown weak relationships between self-reported aggressive driving and self-reported involvement in crashes (Dahlen et al., 2012; Stephens and Sullman, 2015; Sullman et al., 2007, 2015, 2019). This is also evident for professional drivers (Sullman et al., 2002, 2013). A large population study of almost 13,000 Canadian drivers showed associations between the severity of aggression and crash involvement (Wickens et al., 2016). In their study, drivers reporting no aggression had lower odds of being crash involved, compared to those reporting minor aggression (OR = 0.65, 95% CI: 0.54–0.79), whereas those reporting both minor (e.g., shouting, swearing, or gesticulating) and serious driver aggression (e.g., threatening to hurt a driver or passenger in another vehicle) had around 80% higher odds of crash involvement, compared to those reporting minor aggression only (OR: 1.78; 95% CI: 1.04–3.03).¹

There has been criticism of self-report studies that aim to understand the relationships between behavior and crash outcomes.¹ The primary arguments are that self-reports may reflect (1) the frequency of driving, not the behavior and (2) are open to

¹ We refer the interested reader to the published commentary debate regarding the driver behaviour questionnaire and relationship with crashes (see DE WINTER, J. & DODOU, D. 2012. Response to second commentary on "The Driver Behaviour Questionnaire as a predictor of accidents: A meta-analysis". *Journal of safety research*

confirmatory bias leading to under-reporting, which is reflected in weak relationships between behavior and crashes. De Winter and Dodou (2012) provide persuasive evidence regarding the validity of the relationships that have emerged between self-reported driver behavior and crash outcomes, demonstrating that the relationships that emerge are weak because crash involvement is relatively rare. Specific to aggression, the relationships that have been found in survey research have been supported through methodologies using objective behavioral measurements, such as driving simulators (Deffenbacher et al., 2003; Stephens and Groeger, 2009), microtraffic simulations (Habtemichael and de Picado Santos, 2014), naturalistic driving studies (Dingus et al., 2016) and crash data analysis (Conner and Smith, 2014; Paleti et al., 2010).

Using objective crash data, aggressive driving has been shown to significantly increase the odds of crash involvement, with estimates ranging from a threefold increase (Habtemichael and de Picado Santos, 2014) to a 35-fold increase (Dingus et al., 2016). Furthermore, microscopic traffic simulation has shown drivers are three to six times more likely to crash when being aggressive (Habtemichael and de Picado Santos, 2014). Considered across specific behaviors, according to Habtemichael and de Picado Santos (2014), the odds of crashing are fourfold when speeding or weaving in and out of traffic and sixfold when tailgating.

Particularly compelling evidence for the relationship between aggression and crash involvement comes from Naturalistic Driving Studies (NDS), in particular the Second Strategic Highway Research Program (SHRP2) conducted in the USA (Antin, 2011). SHRP2 included vehicle sensor data and video data both from within and outside the vehicle, thereby offering a rich source of objective information regarding the types of aggressive events and the associated effects on driving performance (e.g., crashes). This highlights the fact that NDS are the most ecologically valid method to understand aggression within the driving context. Using the SHRP2 data, Dingus et al. (2016) found that drivers have 35 times the odds of being crash involved (95% CI = 17–70) when aggressive, than they do when not driving aggressively. These odds are comparable to when driving impaired by drugs or alcohol (36 times the odds [OR]; 95% CI = 17–76) and are considerably higher than overall distraction (OR: 2; 95% CI = 1.8–2.4) or distraction when dialing a hand-held mobile phone (OR: 12; 95% CI: 6–26). The confidence intervals indicate that, compared to distraction, aggression was a less frequent behavior, but with greater risks. However, considerably more research has been undertaken into driver distraction than driver aggression,² despite the increased risk presented by the latter.

Aggressive driving not only contributes to crash risk, but has also been shown as an exacerbating factor for injuries resulting from a crash (Conner and Smith, 2014; Paleti et al., 2010). Conner and Smith (2014) used hospital and crash records to estimate that 15% of people involved in aggressive driving crashes in Ohio (2005 and 2009) sustained injuries requiring hospitalization. Paleti et al. (2010) used data collected from 2005 to 2007 for the National Motor Vehicle Crash Causation Study in the USA to understand the relationship between aggressive driving and injury severity. They estimated that 31% of all nonincapacitating injuries and 14% all incapacitating or fatal injuries that occurred during the period could be attributed to crashes from aggressive driving. Therefore, there is consistent evidence to show aggressive driving contributes to crashes and to crashes involving injury.

Aggressive Drivers

Aggressive drivers tend to be younger and male (AAA Foundation for Traffic Safety, 2016; Conner and Smith, 2014; Deffenbacher et al., 2002, 2003; Stephens and Sullman, 2015; Sullman, 2015; Sullman et al., 2013, 2015, 2018; Paleti et al., 2010; Wickens et al., 2011). Indeed young males also tend to be over-represented in crash statistics (Li et al., 2003).

Unlike aggressive driving behaviors, research into aggressive drivers often focuses on the individual's intention or motivations for their behaviors. Aggression can be considered as a response to anger-provoking situations (Deffenbacher et al., 2002) or may form part of a more problematic driving style. The latter may include other illegal behavior patterns, such as drink driving (Paleti et al., 2010), speeding and mobile phone use (Stephens and Fitzharris, 2019; Wickens et al., 2011).

As highlighted in the prevalence statistics, aggressive drivers are unlikely to be aggressive every time they drive. Instead, aggression is a dynamic concept that relies on a unique combination of the person and the situation (Stephens and Groeger, 2009). This is best described using the general Aggression Model (GAM; Anderson and Bushman, 2002; see Fig. 2)

The General Aggression Model for Aggressive Drivers

As can be seen in the GAM (Anderson and Bushman, 2002), aggression relies on the emotional response a driver has to a situation (routes). This response will differ according to who the driver is and the circumstances of the situation (inputs). The resulting behavior (outcomes) will also depend upon the emotion-based appraisals made by the driver, who will evaluate what response is appropriate and the risk involved. An additional element of the GAM is that aggression provides a feedback loop, whereby successful outcomes, for example speeding past a slower driver, are likely to reinforce future aggressive behaviors.

Few studies have comprehensively examined aggressive drivers through the GAM model. However, a large amount of research has been conducted to understand isolated components of this model. This includes driver and situation factors leading to anger and aggression, how anger influences appraisals relating to the situation and appropriate responses, and the relationships between anger and aggression. Each of these are discussed below.

² *Scopus search on "aggressive driving" revealed 2,541 documents, compared to "driver distraction" with 5,915 (performed March 2020)

Figure 2 Representation of the General Aggression Model (Anderson and Bushman, 2002) for aggressive driving.

Driver and Situation Factors Leading to Anger and Aggression

Certain types of drivers are more prone to anger, and certain situations are more anger provoking than others (Deffenbacher et al., 1994). The Driving Anger Scale (DAS; Deffenbacher et al., 1994) is a widely used measure to understand a driver's tendency to become angry while driving (referred to as trait driving anger).³ The DAS measures the likelihood of becoming angry across six types of situations: slower lead drivers, traffic delays, hostile gestures from other drivers, police presence, discourtesy from others and illegal driving. The DAS has been used extensively to understand trait driving anger in a number of countries, including: New Zealand (Sullman, 2006), Europe (Björklund, 2008; Villieux and Delhomme, 2007), the UK (Lajunen et al., 1998), Asia (Li et al., 2014; Sullman et al., 2014), Turkey (Sullman et al., 2013), and Ukraine (Sullman et al., 2017). These studies have consistently shown that younger drivers tend to report more anger propensities than older drivers. This aligns with the age differences noted in both the prevalence of aggressive driving and overall crash statistics. Interestingly, when gender differences are found for anger tendencies, it is women who report higher anger than men (see Deffenbacher et al., 2016; Sullman, 2006). This misaligns with the fact that men tend to exhibit more aggressive behaviors than women and suggests other factors mediate the relationship between anger and aggression.

Research using the DAS has also shown that anger provoking situations vary across traffic cultures, and as such some researchers report different factor structures of the DAS (see Deffenbacher et al., 2016). For example, many researchers find police presence induces low levels of anger. However, situations that consistently provoke anger tend to involve progress impediments, perceived risk and hostility from other drivers (Deffenbacher et al., 2016). Stephens et al. (2019) recently developed the Measure for Angry Drivers to assess anger in modern day driving. They concluded that the three main types of anger-provocation situations continued to be progress impediments, danger from others and hostility. Thus, while the driving task and environment has changed considerably since the DAS was developed, the types of anger provoking situations have remained relatively constant. The only change is that some triggers relating to modern driving (i.e. other's being distracted at, traffic lights, by their mobile phone) are now included in the broader classifications, such as progress impediments.

In-line with the GAM, which suggests anger results from a combination of driver and situational factors, relationships between overall anger tendencies and general anger experienced while driving, tend to be moderate (Deffenbacher et al., 2003). Moreover,

³ We refer the interested reader to DEFFENBACHER, J., STEPHENS, A. & SULLMAN, M. J. 2016. Driving anger as a psychological construct: Twenty years of research using the Driving Anger Scale. *Transportation research part F: traffic psychology behaviour*, 42, 236-247. This provides a review of the research using the DAS

anger prone drivers do not report anger across every situation. Stephens and Groeger (2009) measured levels of anger while drivers drove in a simulator and found that anger propensities were unrelated to reported anger when driving in anger provoking situations. However, in relatively innocuous situations, drivers more prone to anger did report higher levels of anger. This again supports the theory that the relationship between trait anger and anger experienced is mediated by individual and situational factors.

Other driver characteristics can also influence the level of anger experienced and subsequent aggression. Personality traits related to both include: impulsiveness (Dahlen et al., 2012), sensation seeking (Stephens and Sullman, 2015), rumination (Suhr and Nesbit, 2013) and aggressive tendencies (Berdoulat et al., 2013). Lower levels of agreeableness (Dahlen et al., 2012), conscientiousness and emotional stability (Chraif et al., 2016) and higher levels of neuroticism have also been found to be associated with higher levels of anger and aggression (Iancu et al., 2016).

Driver Anger and Appraisal Tendencies

Not all angry drivers will display their anger aggressively. According to the GAM, this is due to the appraisal tendencies made while driving. The initial appraisals are instantaneous and rely on quick assessments of the situation in terms of its relevance and inconvenience to the driver, who is to blame and how legitimate their behavior was (Lerner and Keltner, 2001). The second stage of the appraisal process assesses perceived control and ability to overcome the situation through action. These processes often rely on pre-existing schemas or stereotypes (Allen and Anderson, 2017).

Driver appraisals are also influenced by mood. When angry, drivers may rely on more stereotypical evaluations (Stephens and Groeger, 2011) and make evaluations based on their current mood, rather than the circumstances. One example of this is that drivers in an angry mood are often more likely to have hostile thoughts about other drivers, or to attribute blame for situations that are beyond their control (Stephens and Groeger, 2014). This is exacerbated by the fact that many drivers tend to perceive other drivers as less skilled (Stephens et al., 2016b) and act aggressively to those of lower status (Stephens and Groeger, 2014). Thus, the appraisals made by drivers, influenced by driver state, determine whether there is an aggressive outcome and the form that this takes. These appraisals can be more significant in the determination of aggression, than one's anger tendencies (Stephens et al., 2016a).

Relationships Between Anger and Types of Aggression

A common tool to measure self-reported aggression is the Driving Anger Expression Inventory (DAX; Deffenbacher et al., 2002). The DAX has three types of aggressive responses to anger: verbal aggression (such as yelling at another driver); personal physical aggression (such as getting out of the vehicle to confront another driver); and using the vehicle to express anger (such as following too closely or speeding up). The DAX also includes items to measure adaptive or constructive responses to anger (such as telling yourself to ignore it). To date, there has been an overemphasis on the dangerous types of aggression, with relatively little research on predicting positive behaviors. However, research consistently shows that drivers most commonly try to deal with anger in a positive or constructive manner (Deffenbacher et al., 2002; Sullman, 2015; Sullman et al., 2013, 2015), with the aggressive forms of responses being less frequent.

Two recent meta-analyses reviewed the anger-aggression relationships (Bogdan et al., 2016; Zhang and Chan, 2016). Bogdan et al. (2016) compared 51 studies using self-reported anger tendencies with aggressive expressions of anger. Several of the included studies measured aggression using the DAX. They found that the strongest relationships were between trait anger and verbal expressions of anger, which they argued may be due to the ease of this form of communication. It may also be that other more aggressive forms of responses are often appraised as not being appropriate or viable for the situation, while verbal aggression is a versatile response type. Zhang and Chan (2016) examined the strength of relationships between anger and aberrant driving behaviors, including aggression. They also included 51 studies in their review and found that trait driving anger was related to aggressive, risky driving and driving errors, with the strongest relationship being between anger and aggressive driving. In both of these meta-analyses only weak to moderate relationships were noted. Furthermore, these consider only general tendencies for behavior, rather than more situation specific responses. Thus, while these studies could be more nuanced, they still provide a useful tool to understand the contribution of trait anger to different types of aggressive responses.

Strategies for Reducing Anger and Aggressive Driving

The GAM shows us that it is not the situation that leads to anger and aggression, but how the driver evaluates the situation. Thus, effective strategies for the reduction of anger or aggression lie in targeting the appraisal process. This can be achieved through cognitive strategies and training, key messaging and enforcement.

Cognitive strategies focus on changing the stereotypical response or negative schemas regarding other drivers and their behaviors⁴ (Deffenbacher, 2016). These may also include shifting the focus of drivers. Indeed, Stephens and Groeger (2009) found that

⁴ For a full description of cognitive strategies, we refer the interested reader to DEFFENBACHER, J. L. 2016. A review of interventions for the reduction of driving anger. *Transportation research part F: traffic psychology and behaviour*, 42, 411-421.

drivers who were asked to focus on the anger provocation in each situation had worse driving performance than those asked to rate the danger or difficulty. Mindfulness or resilience training may also offer promising results for the reduction of emotional reactivity. Increased mindfulness has been associated with less anger and aggression in drivers (Kazemeini et al., 2013; Stephens et al., 2018), while increased resilience has been associated with more adaptive ways of dealing with anger (Gras et al., 2016).

Enforcement also plays a key role in behavior change. The NHTSA found targeted enforcement led to a reduction in the proportion of aggression-as-the-primary-factor in crashes (Stuster, 2004). Evidence from other illegal behaviors, such as speeding and drink driving shows that drivers who engage in these behaviors do so because they do not perceive they will get caught and also underestimate the risk (Stephens et al., 2017a, 2017b). However, the risk of aggressive driving may be less clear, as a result of the inconsistency in defining it. This highlights the importance of clear definitions and proxy behaviors to operationalize it, as well as the need for this to be communicated to drivers.

Anger and Aggression in Autonomous Vehicles

While the role of anger in aggressive driving is now well established, it is less clear how emotions will influence driver operation in autonomous driving. This will be particularly relevant in the lower stages of automation, where drivers will still be required to take-over the driving task. There are some data to suggest that AV may provide a promising solution to the aggressive driving problem. Research has shown that drivers who acknowledge being angry and aggressive would readily accept in-vehicle systems designed to intervene and dissipate potential aggression in manual vehicles (Li et al., 2020). In particular, drivers report that auditory warnings that have a family member's voice would assist in reducing aggressive responses. However, studies of mood during AV driving have shown that a driver's mood can deteriorate during complex driving (Techer et al., 2019). The effects of this on take-over responses are not yet known. Finally, we do not know whether AV will be the solution for anger and aggression, or a tool that exacerbates this.

Conclusions

Aggression and driving anger are genuine road safety concerns, but there is currently no agreed definition of aggression. Road safety agencies use proxy behaviors that can be indicative of aggression to understand the problem, but these proxy behaviors vary across agencies and drivers may not know these behaviors are enforceable. In contrast, researchers often focus on aggressive drivers, trying to understand factors associated with their deliberate aggressive behaviors. Although both approaches are equally important, understanding intent allows the development of strategies to reduce aggression. These strategies are likely to be effective in changing how drivers appraise and respond to various driving situations. Nevertheless, enforcement can only be carried out on observed behaviors, irrespective of intent. Finally, we do not currently know the role that anger and aggression will play in transitioning or adopting AV; however, the evidence gathered to date suggests that AVs can be used to support drivers and to reduce anger and aggression.

Introduction

Roads are a public good, most often paid for by public funds. Licensed drivers can drive anytime and go anywhere on them. We are free to do these things as individuals, taking advantage of the public space. Roads are a “commons” (Baden & Noonan, 1998). But commons’ spaces are often abused, for freedom to use them at will without perceived consequences for breaking rules lead to what Hardin (1968) termed the “tragedy of the commons” (p. 1244): the freedom of individuals abusing the commons, acting in their own self-interests without restraint, leads to ruin.

Porter and Berry (2004) argued abusing the roadway commons was a possible explanation for aggressive driving. Specifically, while we can use roads whenever and wherever we please, there are rules for that use. When those rules are broken in some cases, the abuse leads to risk for traffic crashes as well as for provoking aggression and anger in other road users. One rule-breaking behavior contributing to the commons’ tragedy is speeding. As Porter and Berry discussed, aggressive speeders use the road as their own property, ignoring the shared needs of others, in making weaving actions or placing others in harm’s way if they lose control of their vehicles. Such an individual’s behavior can benefit them at the expense of others, and when risk turns into crashes the commons has been ruined for all (particularly when lives are lost).

Our chapter continues this focus on speeding. We differentiate between “speeding” and “speed.” “Speeding” behavior involves driving at speeds that exceed a posted limit and are risky given conditions of the road, conditions of the vehicle, presence of other vehicles, pedestrians, or bicyclists, or other considerations. Speeding does not require an absolute numeric threshold, but rather a speed level that increases the likelihood of a crash. “Speed,” on the other hand, is just that: an absolute quantity that by itself does not imply or predict risk.

Speeding as a cause of fatal crashes is well-established. For example, in the United States (our home country), at least one driver was speeding in 26% of traffic fatalities (2018 data, latest available; National Center for Statistics and Analysis, 2020). In Virginia, our home state, speeding was involved in 42.2% of traffic fatalities (in 2019, latest data available; Virginia Highway Safety Office, 2020).

There are significant economic impacts, too. In the United States, the economic costs of speed-related crashes were \$52 billion in 2010, or an average of \$168 per person (Blincoe et al., 2015; also see CDC, 2014). Developing countermeasures to reduce speeding is worth the efforts required for public safety and economics.

Our chapter provides the latest, best practice information for understanding speeding’s prevalence as well as its countermeasures. Our goal is to produce concrete suggestions for how the behavior is shaped so that readers know how to build programs to address its reduction. However, for readers who wish to know more of the history and theoretical developments behind how the field developed these latest applications, we first provide a framework upon which the review is structured.

Review Framework

Speeding is a widely studied behavior from multiple disciplines. We simply cannot cover the full history in a brief chapter, nor a full coverage of all disciplines involved. We contain our review to published material mostly since 2011, roughly the past decade with few exceptions. Strategically, the current review adds to one we published previously, with readers encouraged to consider that earlier work for a longer-term understanding of speeding (Berry et al., 2011).

Table 1 Antecedents and consequences for speeding behavior

Category	Subcategory	Example	Reference
Antecedent	Structural—person	Age: sex/gender	Younger more likely than older Younger males and females in urban areas and younger males in rural areas more likely to speed. Men are 50% more likely than women to drive over speed limit Doroudgar et al. (2017), Richard et al. (2018), Richard et al. (2012)
	Structural—environment	Road design: roadway type	Roadway configuration and visual cues can alter speed (e.g., traffic calming) Travel speeds are lower in urban than suburban and rural areas on all road types Ewing (2017), Neuner et al. (2015), NHTSA (2018)
	Rules	Traffic norms perceptions/expectations	Speed limits impact speeding Safe speed influence by expectation of what would trigger a citation AutoInsurance Center (2020), Mannering (2009)
Consequences		Convictions	Citations reduce crashes 6% and violations 8%. Other research studies show no impact on receiving future citations Masten and Peck (2004)
		Crashes	At least one speeder in 26% of traffic fatalities in Virginia, speeding involved in 42.2% of traffic fatalities National Center for Statistics and Analysis (2020), Virginia Highway Safety Office (2019)
		Economic costs	Annual estimated cost of motor vehicle crashes in USA = 50 billion dollars Blincoe et al. (2015)

We organize material using the behavior-analytic model, a useful approach for understanding how behaviors impact public health injury risk (Sleet et al., 2006). Behavior analysis, or its large-scale partner, behavioral community psychology, focuses on antecedents leading to speeding and the consequences that follow which either increase or decrease the future likelihood of speeding. Further, our main interests are associated with observed speeding, not self-reported behaviors or reports of intention to speed.

With our goal to give the reader practical guidance, the review targets effective countermeasures that reduce speeding. We highlight countermeasures that also reduce crash and injury risk from speeding. To be even more consistent with modern trends in traffic psychology, we discuss the traffic culture context (Özkan and Lajunen, 2011). Scholars are acknowledging more commonly, and we believe finally so, that not all countermeasures are effective or generalize beyond their initial developmental setting and time. Culture impacts effectiveness.

Then, we conclude the chapter with our recommendations for next steps in speeding research. We lay a possible pathway for a future chapter to be written to update the one you are reading.

What We Know

The following are antecedents that predict and consequences that impact the likelihood of future speeding. These are the tools through which we can impact speeding. They are briefly summarized in text, but then presented in Table 1 for easy reference. In addition, they are organized by categories suggested by Mattaini (1996) to understand behavior within a cultural context.

Speeding Antecedents

Structural. Mattaini (1996) suggested structural antecedents could be categorized into those related to the *person* or *environment*. For the former, demographic variables are common antecedents. Consider roadways as congregate areas whereby people populate streets, roads, highways as drivers, passengers, and other road users with inherent demographic and motivational diversity. Over the years, age-related speed patterns have emerged in both attitudinal and behavioral measures. Young driver attitudes toward speeding tend to be more positive than older driver attitudes. This cognitive difference correlates consistently with age-related speeding behavior as observed in speed-related crashes.

Additionally, speed-related differences extend to gender differences among younger drivers. For instance, younger teenage men are more likely than teenage women to speed (38% vs. 25%, respectively; see Swedler et al., 2012). Younger men and women in urban areas are more likely to speed than those in rural areas (Doroudgar et al., 2017; Richard et al., 2018).

Gender, independent of age, also makes a difference. Men show consistently higher indices of risky behavior and the consequences associated with such risk taking. For each year from 1982 to 2018 male drivers were more likely than female drivers to be

involved in a speeding related fatality (FARS Data, posted 2019; [Insurance Institute for Highway Safety \[IIHS\], 2020](#)). Additionally, men as compared to women have further comorbidities including a greater likelihood to drive while intoxicated that involves the driver’s death. Also, men as compared to women report both using their cell phones and texting while driving in greater rates ([Forgays et al., 2014](#)). Because the activity of regulating speed is a primary task of a driver, factors playing a peripheral role but are none-the-less influential on driver attention, vigilance, decision making, and vehicular control should be considered in understanding the nature of a speeding driver.

For an environmental example, roadway type can impact speeding. Urban roadways have lower speeds on average than suburban and rural roadways (NHTSA, 2018).

Rules. Communities initiate traffic-safety laws to regulate the risk taking of drivers, and as such laws are a special type of countermeasure when setting speed limits and enforcement parameters. But laws as countermeasures derive their influence over behavior as socially derived and presented antecedents. Here, the antecedent law functions as an announcement to inform the public about a behavioral contingency. For instance, a speed limit sign posts a number indicating an upper end driver speed, but the sign is a symbol of a law indicating the potential consequence for violating the speed limit (a fine). When laws have been long established, they also can be a social norm (i.e., rule-governed behavior). When correlating different US state speeding laws with FARS’ speed related deaths, the type of law was seen to moderate a state’s population of driver speed ([AutoInsurance Center, 2020](#)).

Speeding Consequences

Crashes, injuries, fatalities, and economic decrements are important consequences of a speeding-related traffic crash. Such consequences were mentioned earlier in this chapter. Another type of consequence, traffic citations for speeding, is certainly one that can be manipulated as a countermeasure with effectiveness. We turn now to countermeasures—those actions communities can do to reduce speeding on their roadways. A summary of countermeasures is in [Table 2](#).

Table 2 Countermeasures to reduce speeding behavior

Category	Descriptor	Example	Reference
Education/ media	Media publicity Goal setting/social norming	Publicity campaign focused toward speed less effective than alcohol targeted Pilot study showed short-term improvement in compliance with speed limits	Phillips et al. (2011) , Newman et al. (2014)
Engineering	Road design Speed limiters Intelligent speed adaptation Autonomous vehicles	Roadway configuration and visual cues can alter speed Device restricts maximum speed. Study of speed limiters on 20 commercial vehicle fleets showed ~50% reduction in crash rate compared to truck without the limiters Vehicle adjusts to the speed limit or warns driver when over the speed limit. Small but lower proportion of drivers speed 8 or more mph over limit when using warning device. Speed alerting and speed controlling devices were effective at reducing speed of serious speeders in Netherlands, but one removed speeding returned Vehicle controls speed improving fuel economy and travel time, reducing crashes	Edquist et al. (2009) , Hanowski et al. (2012) , De Leonardis et al. (2014) , Van der Pas (2014) , Anderson et al. (2016)
Enforcement	Speed limits Variable speed limits reducing speed limits high-visibility Enforcement (HVE) automated enforcement	Higher speed limits associated with more fatalities Lower speed limits associated with fewer crashes, injuries, and fatalities. 3 mph reduction in average speed on a 30 mph road is expected to reduce injury crashes by 27% and fatal crashes by 49% Each 5 mph increase in state max speed limit, fatality rates increased 8% on interstates and freeways and 4% on other roads. Speed limit varies based on traffic and weather conditions. Preliminary study of Wyoming freeway VSL lead to reduction from 0.17 to 0.75 mph for every mph reduction in speed limit. Increasing number of localities are dropping speed limit citywide or on corridors to reduce crashes and severity of crashes. Reducing citywide speed to 20 mph in Bristol, UK, was associated with 63% reduction in fatal injuries. Enforcement and media used to highlight enforcement effort. Limited success as requires high levels of enforcement efforts Citation issued based on set number of mph over speed limit—consistent consequence. Reduction in the number of crashes. 20%–25% reduction in injury crashes. 8%–49% reduction for all crashes, 11%–4% for serious injury and fatal crashes. France installed 2756 cameras between 2003 and 2010 which is estimated to have prevented ~15,000 fatalities	AASHTO (2010) , Farmer et al. (2010) , Buddemeyer et al. (2010) , Bornioli et al. (2020) , Blomberg et al. (2012) , Decina et al. (2007) , Wilson et al. (2010) , WHO (2017)

Speeding Countermeasures

Education. Speeding education is used with all age groups. Predrivers receive the bulk of speeding related education via driver's education courses and driving tests. However, not every such education program has shown effectiveness in reducing speeding. For example, Phillips et al. (2011) found such programs were less effective for speeding than for alcohol and driving.

Another education-based countermeasure has used goal setting and social norming. Newman et al. (2014) evaluated this countermeasure's impact with a small group of industry drivers and demonstrated reductions in their speeding.

Engineering. Engineering countermeasures can be designed into the environment to reduce speeding. The most common methods include setting appropriate speeds, road design, and traffic controls. Setting appropriate speeds weighs safety and travel efficiency objectives (Forbes et al., 2012). Higher limits are associated with higher fatalities. In fact, a three-mph reduction in average speed on a 30 mph road can reduce injury and fatality crashes by 27% and 49%, respectively (ASHTO, 2010). Reducing speed limits has been linked to lower speeds on freeways (Buddemeyer et al., 2010) and within cities (Bornioli et al., 2020). And, when state maximum speed limits increase negative consequences follow. For each 5 mph increase, fatality rates increased 8% on interstates and freeways and 4% on other road types (Farmer et al., 2010). Reducing city limits to 20 mph in Bristol, UK produced a 63% reduction in fatal injuries (Bornioli et al., 2020).

Road design is considered with setting speed limits. Road design directly influences travel speeds with wider, straighter, more open roads spurring higher speeds than narrower, curved, and roadside-cluttered roads. Simple reconfigurations such as narrowing roadway markings, adding chicanes, or road diets reduce speed (Ewing, 2017; Neuner et al., 2015). Traffic controls can also aid in limiting speed. Road corridors or segments can be timed so that signal lights allow for maximum traffic flow when speed limits are obeyed (De Gier et al., 2011).

Other engineering countermeasures target the vehicle itself. Speed limiter devices can be installed to prevent going over a certain speed. These devices are typically found in school buses and commercial vehicles (Hanowski et al., 2012). Other devices can be installed that provide feedback when the driver goes over a certain speed. While such a device does not restrict speed, it provides a tactical, visual, or auditory alert (De Leonardis et al., 2014). Newer devices and apps allow parents to monitor their child's driving behavior, including speeding (Farmer et al., 2010). For lower volume conditions on road stretches without traffic controls, cruise control helps regulate the individual vehicle's speed.

More recently, technology is being developed and refined to implement intelligent transportation systems (ITS) where all vehicles and road users are linked together through infrastructure to help improve the safety and efficiency of roadways. Autonomous vehicles are the latest innovation being tested for such a system. While a fully automated vehicle fleet is decades in the future, automated vehicles could be programmed to follow speed limits and maintain following distances which could reduce speeding related crashes, fuel economy, and travel time all together (e.g., Anderson et al., 2016).

Enforcement. The most common countermeasure for speeding that applies consequences to the behavior in an attempt to prevent its future occurrence are the millions of citations issued by law enforcement officers each year resulting in fines and possibly court costs totaling hundreds of dollars (Mashhadi et al., 2017). Using citations attempts to deter speeding based on the fear of consequences. High visibility enforcement is an often-used technique combining enforcement and media outreach to promote the message that officers are out in force issuing citations. And there is evidence that these efforts can reduce speeding and its resulting crashes (Masten and Peck, 2004). But the success may require high levels of effort (Blomberg et al., 2012).

While law enforcement cannot issue citations to every motorist speeding past, speed cameras (automated enforcement) offer a consistent method to issue citations. Speed cameras allow a threshold to be set after which every motorist passing the location above the threshold is issued a citation. Public acceptance of speed cameras and traditional speed enforcement can be improved by ensuring that enforcement locations are data-driven, fair, and consistent with the goal of preventing crashes. And, in fact, these cameras are effective at reducing injury and fatal crashes (Decina et al., 2007; Høye, 2015; Wilson et al., 2010). In France between 2003 and 2010, speed cameras were linked to 15,000 prevented fatalities (WHO, 2017).

Countermeasure Barriers

The scholarly community has known the major antecedents and consequences for years. Countermeasures have been developed and tested as new technological innovations (e.g., photo enforcement) have been introduced, but the basic understanding has not changed. Rather, what is clear is that the largest issue with reducing speeding is to develop a countermeasure, and deploy it, in ways that breakthrough barriers created by other variables not regularly or fully incorporated in speeding studies: cultural differences and political will.

Traffic Safety Culture

Traffic safety culture, as a construct, is described by Özkan and Lajunen (2011) as bringing the person and environment interaction into traffic safety's sphere. Much like Lewin (1936) discussed behavior being a function of person in the environment, traffic safety culture considers how one's driving and walking behavior are dependent to some level on the environment in which those behaviors occur.

Özkan and Lajunen give many examples of how different levels of culture impact countermeasures' impacts on road safety (from the immediate environment of a person through to influences on citizens unique to their countries). Resources available to a state or

country influence road development, technological innovation, vehicle design, and economic support for countermeasures of varying costs. There are differences in governmental foci, educational opportunities, and urban versus rural spaces among different levels that also create cultural differences in public health. Such differences impact road safety outcomes.

While not a behavioral study, but rather a self-report one assessing drivers' violations and errors, Özkan et al. (2006) found that countries considered “safe” (Britain, The Netherlands, Finland) had drivers who reported more speeding on motorways than drivers from “dangerous” countries (Turkey, Greece, and Iran). Motorway speeding seemed to occur on better-constructed roads and was related to the amount of enforcement present. However, dangerous countries' drivers reported more aggressive driving acts and errors. The authors concluded less developed infrastructure, lower norms, and stress created the worse driving reports for the dangerous countries.

Acknowledging that cultural differences are important, countermeasures can be tailored to address influencers of a targeted area. Role models, particularly those who live in the same area of concern for the countermeasure, could demonstrate the behavior that is expected to increase safety. Such indigenous change agents (Roger, 1995) can be more effective motivating change than outside agencies or authority figures directing individuals about how to behave.

Political Will

In our experience over years of working with communities to change at-risk driver and pedestrian behavior, one barrier regularly presents itself. This barrier is particularly tall and thick when experts have suggested enforcement strategies for reducing risky driving. Enforcement, as reported here and in other settings, is among the most effective techniques for creating roadway behavior change. However, the will to pass legislation to allow enforcement, to consider automated enforcement in particular, and to listen to and absorb public scrutiny for restricting behaviors perceived by some as a freedom (e.g., freedom to drive faster than a limit on dry roads and no other driver nearby) is key to most successful countermeasures in roadway safety.

Policy makers who effectively garner public backing are successful in their ability to build community relationships and explain the need for legislative action. They too have a budget that can support countermeasures, such as automated enforcement (effective, but initially expensive to deploy). And these policy makers are successful communicating that the goal for their actions is to save lives, not fill the public coffers with citation payments. Professionals who wish to effectively build and launch a countermeasure to reduce speeding in a community, state, or country must have the support of these policy makers who have the political will to back and support the countermeasure. Those partners will also be critical in maintaining the gains of any countermeasure that is effective, for once professionals move on to other issues the policy makers remain to create legislation, allocate budgets, or both to ensure the countermeasure remains (e.g., automated enforcement) and gains sustained, or whether the risky behavior is likely to return.

Next Steps for the Speeding Researcher

The review provided here has two major conclusions. First, much of what we know about speeding and to reduce it to reduce injuries and fatalities has not changed from previous reviews. Appropriate road design, properly set speed limits, and strong enforcement programs that include automatic enforcement where feasible can reduce the harm caused by speeding behavior. Newer technologies, most notably autonomous vehicles, show promise for the future control of speeding. However, autonomous vehicles are not yet widespread to impact community-wide speeding outcomes.

Future researchers can make the biggest impact in the field by focusing on two topics. First, with the future technology in consideration, they can investigate what infrastructure needs will be required to properly use autonomous vehicles. While these vehicles will not solve all speeding concerns, nor do they remove fully the role of the human in driving risk, it seems clear the technology will only grow in importance. Researchers must not assume the speeding issue will disappear, and in fact while we have a mixed environment (human and machine drivers), the role of speeding may lead to worse outcomes if the speed variances on roadways increase.

Second, the importance of traffic culture and political will create tremendously important research opportunities. Countermeasures should be designed with both in mind; there may be regions where automated enforcement simply will not be accepted, leaving high-visibility enforcement the remaining best practice. There will be a greater need for researchers to test such adaptations and make no assumptions that everyone will be willing or able to use all countermeasures. What is not well known is how traffic culture moderates the effectiveness of countermeasures. Worse, there is even fewer research studies on the role of political will on countermeasure adoption. This one area alone would be well-worth a focus for a scholar's career.

In closing, we predict that the next review of speeding behavior and countermeasures will read much the same as this one and the earlier chapter we wrote (Berry et al., 2011) unless researchers take more time now on infrastructure, culture, and will. We look forward to the possibility that we will see such research take center stages in our journals soon.

Introduction

Cycling reduces mortality risk by 10%-28% and is associated with proven health benefits, including cardiovascular fitness, weight loss, improved cognitive ability, reduced stress, and longer life expectancy (Götschi et al., 2016). Even when considering accident risk and air pollution the health benefits of cycling considerably outweigh the negative externalities (de Hartog et al., 2010). Cycling also contributes to reducing air pollution and greenhouse emissions. Big data from Shanghai show that 1 million bike trips in the city center with an average length of 2.4 km result in CO₂ and NO_x emissions decreasing by 25,240 tons and 64 tons respectively (Zhang and Mi, 2018).

In light of the proven health and environmental benefits, as well as the ability to provide an affordable transport solution and reduce congestion, cities around the world are implementing bike-sharing and bicycle infrastructure solutions (Kaplan et al., 2018a, b). Currently, more than 700 cities operate bike-sharing programs, with the largest ranging between 20,000 and 90,000 bikes (Fishman et al., 2014). The public reaction to these systems is positive, with a 20% reduction in car use, up to three trips per bike daily, trips ranging between 15 and 20 min and up to 3-4 km traveled per trip (Fishman et al., 2014). While cycling in car-oriented countries is still evolving, evidence from Germany shows that cycling in a car-oriented country can rise to 10% nationwide and can exceed 30% in some cities, reaching the level of bicycle-friendly countries (Lanzendorf and Busch-Geertsema, 2014). Yet, policymakers face challenges associated with changes in behavioral norms and long-lasting car-oriented urban design. The common expression “if you build it, they will come” is used to justify investing in cycling infrastructure in places with low cycling rates and motivate the implementation of bike-sharing schemes, which is often coupled with limited cycling infrastructure (Félix et al., 2019). Policymakers facing such decisions need to promote changes in travel habits and norms as well as implement major changes in urban design and infrastructure. Hence, policymakers are concerned about the regional transferability of successfully promoting cycling habits. Many research and policy frameworks overlook two important aspects of cycling: motivations and trip satisfaction (Willis et al., 2013). The traditional perspective views regional differences in the success of cycling promotion as a result of spatial development patterns, transport and land-use policies, and cultural norms (Lanzendorf and Busch-Geertsema, 2014). However, this does not sufficiently support the transferability of cycling habits across regions and the ability to recreate the success of cycling-friendly countries. Three questions remain: if you provide cycling infrastructure, will they cycle? Will they also cycle under conditions of partial implementation? Can we effectively promote cycling in a gradual manner? The answers to these questions are embedded in motivational psychology. Unlike infrastructure design characteristics that depend heavily on local conditions, or a change in cultural norms that requires decades, motivational psychology can be generalized and is readily transferable across regions.

Behavioral Motivation

The ability to generalize behavioral motivation is fundamental to designing effective cycling policies and campaigns. While cycling can be discussed from a pure cost-benefit perspective (e.g., Wardman et al., 2007), it is better understood through discussing the broad sense of utility and travel satisfaction. Short-term trip-based mode choice is traditionally explained by functional monetary and time gains, which only partially explain cycling as a mode choice. Health benefits and hazards are also part of economic decision-making, although they are often difficult to calculate and perceive and are sensitive to temporal myopia bias. Rationalizing both excess car use and cycling has contributed to the development of a holistic and pluralistic utilitarian perspective that encapsulates general motivational theories and expands utility from “gain” and “loss” to “satisfaction” and “difficulty” (Gärling and Axhausen, 2003; De Vos et al., 2019).

Figure 1 The habit formation loop.

The term “satisfaction” encompasses the opportunities in terms of time and monetary gains, health benefits, immediate rewards associated with hedonic enjoyment, and long-term rewards associated with self-concepts and general mood. Satisfaction can be viewed as the satisfaction of functional, social relatedness, and personal growth needs that form the basis of attitude formation (Alderfer, 1969) and the three-dimensional goal framing theory based on functional gain, normative, and hedonic values (Lindenberg and Steg, 2007). In contrast to the classical assumption that functional gains are the main motivators, higher-order needs and emotions can act in synergy or competition with functional values. Satisfaction also enables the broadening of the scope of utility to include the “new mobilities” paradigm (Sheller and Urry, 2006), which suggests that travel contributes to identity production by meeting higher-order needs of independence, self-actualization, self-esteem, and social relatedness. Satisfying social relatedness needs integrates conforming to social norms within the broader sense of satisfaction, thus adding the external motivation of subjective norms. The term “difficulties,” as the complementary pillar to “satisfaction,” refers to the perceived loss or an unsuccessful result, the perceived ability to perform an action, and the amount of volitional control (Ajzen, 1991). Cycling presents a broad range of potential difficulties, including functional constraints deriving from resource availability and accessibility, as well as physical difficulties and psychological barriers.

Cycling as a preferred choice and the transition to cycling as a habitual choice rely on positive perceptions of the travel experience to initiate the choice and reinforce repeated choice (Brette et al., 2014; Gärling and Axhausen, 2003). Similar to cost-benefit analysis, “satisfaction” and “difficulty,” which lead to the formation of goal framing, attitudes, and personal norms, can be assessed prior to the choice. Following the choice to cycle, derived satisfaction and difficulties are re-evaluated, leading to a habit formation loop upon a gratifying experience, as shown in Fig. 1. A possible form of the habit formation loop, where satisfaction leads to a proactive travel attitude, is documented by De Vos et al. (2019). The following sections describe at length each part of the loop.

Expectations

The Theory of Planned Behavior

The most prevalent guiding framework for internal cycling motivation is the theory of planned behavior (TPB; Ajzen, 1991), which has been applied to explain cycling intentions and behavior. The theory has been applied to examine the propensity of utilitarian and recreational cycling to be the main travel mode, and the acceptance and use of shared bikes and electric bikes. The TPB has been applied across population groups from adolescents to the elderly in both car-oriented and cycling-oriented countries around the world. It has been applied in a cross-sectional analysis to explain behavior at a specific point in time, and it has recently been applied to predict cycling behavior change (Bird et al., 2018; Nkurunziza et al., 2012). While the TPB has been found to be a rigorous approach, a unified scale or instrument has not been developed for its standardized application: application varies with respect to the choice of psychological constructs and measurement items. The TPB has been explored with a qualitative approach (Heinen and Handy, 2012; Janke and Handy, 2019) and validated using structural equation models (e.g., Cai et al., 2019; Fernández-Heredia et al., 2014; Kaplan et al., 2015) and inter-group comparisons between cyclists and non-cyclists (Félix et al., 2019). The TPB has been extended to include complementary dimensions and theories such as habit (de Bruijn et al., 2009), the socio-ecological model (Sigurdardottir et al., 2013), social identity theory (Lois et al., 2015), the technology acceptance model (Chen, 2016), the prototype willingness model (Frater et al., 2017), and the unified theory of acceptance and use of technology (Jahanshahi et al., 2020).

Cycling attitudes considered within the TPB are person-, behavior-, and product-centered attitudes. Human-centered attitudes derive from personal values. Although they are manifested through actions and choice, they are not directly associated with behavior. Examples are environmental attitudes and personal norms. Behavior-centered values focus on the attractiveness of cycling, encompassing perceived expectations regarding the value of cycling in terms of observed advantages and feelings. Behavior-based attitudes are a direct translation of Ajzen's (1991) original model conceptualization and are the most prevalent in cycling studies. Behavior-centered attitudes include normative, gain, and hedonic goal framing and can be cycling specific or comparative measures of cycling versus other modes. Normative goal framing focuses on moral obligation and conforming with personal norms. Gain goal framing focuses on the perception of results, and hedonic goal framing focuses on feelings associated with the behavior. Examples of a normative perspective are "I would pollute the environment less" (Lois et al., 2015) and "I feel morally obliged to travel by bike instead of using other transportation" (Han et al., 2017). Examples of a gain perspective are "cycling helps me save money compared to other transport modes," and "cycling helps me get exercise" (Lois et al., 2015; Sigurdardottir et al., 2013). Examples of a hedonic perspective are "I enjoy cycling" (Lois et al., 2015) and "cycling is interesting/pleasant/stimulating" (Frater et al., 2017). Product-centered attitudes are associated with cycling infrastructure, and with bike-sharing systems' quality, features, and usefulness. Product-based attitudes largely depend on the perceived product image, imagined prototype evaluation, and similarity to existing alternatives (Frater et al., 2017). In the case of cycling and the adoption of shared-bicycle systems, product-based evaluation depends on the subjective image or vision of the system, rather than its objective traits. Hence, product-based attitudes also provide normative, gain, and hedonic framing based on the envisioned system attributes and associated value. Examples of infrastructure-based attitudes are "availability of bikeways along the way" (Gao et al., 2018) and "the route has beautiful scenery" (Winters et al., 2011). Product-based normative goal framing includes ecological and altruistic values. An example is "the environmental performance of the bike-sharing company corresponds to my expectations" (Chen, 2016). Product-based hedonic perceptions correspond with innovative features or a positive experience using the system. Examples are "using the bike-sharing system is relaxing" (Chen, 2016), "I am interested in riding a high-tech electric bicycle," and "electric bicycles are fast and easy" (Kaplan et al., 2015).

Cycling subjective norms refer to the social circle of influence, including significant others (e.g., family, friends, and colleagues), and community social norms based on location, cycling culture, media activity, population strata, and government policies. Social norms include both visibility and word-of-mouth. Visibility refers to behavioral trends and the behavior of significant others, while word-of-mouth consists of conversations about cycling, expressed opinions and thoughts, and appreciation by others. Norms represent the social pressure to conform to expectations, social support and encouragement to do "the right thing," and the hope of becoming an opinion leader in one's social circle. Examples of word-of-mouth in the social circle representing social pressure and encouragement, respectively, are "people who influence my behavior think that I should use bike sharing" and "people who are important to me encourage me to use bike sharing" (Chen, 2016). An example of a community visibility norm is "people usually cycle in the city," while examples of community word-of-mouth are "people think that cycling for recreation is cool" and "my friends are concerned about environmental responsibility" (Kaplan et al., 2015). Examples of community policy norms are "my school encourages environmentally responsible behavior" and "driving in city centers will be banned" (Sigurdardottir et al., 2013).

Cycling difficulties include person-oriented difficulties, situational difficulties and constraints, and product or system-oriented ease-of-use (Fernández-Heredia et al., 2014; Kaplan et al., 2015). Person-based difficulties comprise bike availability constraints, concerns regarding the perceived ability to cycle, lifestyle constraints, and fear of cycling. Availability or accessibility constraints include lacking a bicycle, gear, facilities, and storage space. The perceived ability to cycle entails concerns regarding the required physical effort, physical fitness, and cycling skills or experience. Lifestyle constraints include dress code, trip chaining, traveling with children, the need to carry baggage, and the car as essential commuting or work tool (Félix et al., 2019). Situational difficulties include location-based concerns, unfavorable weather conditions, and parental consent for children and adolescents. Location-based concerns include hilly topography, long-distance, cycling or traffic congestion, quality and availability of facilities, and accident and crime rates (e.g., bike theft, vandalism, and harassment). A product-oriented difficulty is bicycle maintenance. System-oriented difficulties refer to infrastructure and operating the bike-sharing system features, such as using apps, finding the bikes, paying online, and returning the bike.

Perceived risk and fear of cycling in mixed traffic are among the most important barriers to cycling in terms of their prevalence and strength. Fear of cycling is particularly relevant in car-oriented or emerging cycling-oriented countries where cyclists share the road with mixed traffic. While fear of cycling has been incorporated into the TPB as a type of barrier, there is ample research on cycling fear as a standalone concept, its sources, and associated coping mechanisms. Fear of cycling can be measured by the perception of danger associated with cycling in mixed traffic. Recent studies show that fear is a multifaceted construct driven by explicit cyclist-motorist interactions and implicit cyclist perceptions of infrastructure layout and traffic (Chataway et al., 2014). Research on the topic includes cyclist-motorist road interactions and resulting emotions, and cyclists' coping strategies while cycling in mixed traffic. Among the first to identify cyclist-motorist tension were O'Connor and Brown (2010), who identified negative verbal and physical harassment of cyclists by drivers in Australia. These findings were corroborated by Kaplan and Prato (2016), whose results from Israel revealed several sources of driver aggression and three types of cyclist coping mechanisms, with the most prevalent being cycling avoidance. They showed that conflicts between cyclists and motorists involve a high perception of threat that leads to intense feelings of anxiety, fear, and stress, impeding cycling. Later, Möller and Haustein (2017) presented evidence that anger expression among drivers and cyclists also exists in cycling-friendly countries such as Denmark. Following Prati et al. (2017) findings that cyclists are viewed as a minority group, Kaplan et al. (2019b, 2019c) explored the ability of the social interaction theory to explain cycling fear and the willingness of drivers and cyclists to share the road in the Czech Republic and Israel. They found that the

willingness to share the road is associated with cycling cultural norms, the perception of drivers as distracted or aggressive, the perception of cyclists as vulnerable or assertive, and the perceived anger and anxiety resulting from cyclist-motorist road interactions (Kaplan et al., 2019c). The findings show that road infrastructure is needed to establish a safe cycling environment and promote cyclists' "right" to the road. Moreover, cyclist-motorist interactions and perceptions need to change through promoting mutual empathy in order to eradicate fear as a barrier to cycling.

Need-Based Theories

Ho et al. (2015) found that core values associated with cycling among recreational cyclists reflect the ability of cycling to create a sense of happiness and to fulfill basic and higher-order needs including belonging, self-esteem, and self-actualization. They postulated that cycling motivation conforms to the theory of human needs. Alderfer's (1969) ERG theory of needs (Kaplan et al., 2018a, 2018b), social identity (Lois et al., 2015), and Ryan and Deci. (2000) self-determination theory (SDT; Chi et al., 2020; Grayson et al., 2019) were proposed to study cycling motivation. As in the case of the TPB, a unified scale for cycling needs has not been developed and each study provides a different empirical interpretation. The ERG theory of needs postulates that people strive to satisfy existence, relatedness, and personal growth needs. In the context of cycling, existence needs are functional needs related to the ability to carry out daily activity patterns, save resources, gain independence, and maintain a healthy lifestyle. Relatedness needs in the context of cycling refer to belonging to a group or community, socializing, and gaining appreciation from significant others. Personal growth needs in the context of cycling refer to acting in accordance with personal values and promoting personal growth in terms of self-efficacy, competence, and autonomy. The theory of needs allows a non-hierarchical order of needs importance variation across individuals (Alderfer, 1969), meaning that relatedness and growth needs can take priority over functional needs. This is of the utmost importance for cycling as a mode choice, since it explains and rationalizes choices that deviate from the functional superiority embedded in the economic utilitarian approach.

Need-based theories differ from the TPB theory in three respects: (1) they measure attitudes toward the behavior as the ability to satisfy human needs; (2) they focus on social relatedness rather than conforming to social norms; and (3) they consider behavioral constraints that derive from self-efficacy, competence, and autonomy. While the TPB provides non-mediated behavioral motivation that accommodates internal motivation, external pressure, and perceived ability, need-based theories drive the goal framing underlying the TPB attitudinal constructs: the need to function and the need for social relatedness and personal growth. Much like a utility, needs can become behavioral motivators on the basis of expectations regarding the ability of a behavior to satisfy needs. Kaplan et al. (2018a) developed a need-based cycling motivational scale validated in Denmark as a cycling-oriented country and Poland as a car-oriented country (Kaplan et al., 2018b).

Existence needs motivate gain goal framing and thus trigger attitudes based on the ability to satisfy functional gains. Cycling related existence needs include saving time, money, parking search time and costs, getting exercise and fresh air, increasing the number of activities and the locus of opportunities, and relieving stress (Kaplan et al., 2018a). Existence needs relate to functional gains and can make a significant difference in the case of weakened populations and individuals with limited financial resources. They are also highly relevant in cycling-oriented cities, such as Copenhagen, where cycling superhighways, exclusive bicycle pathways and bridges, and bicycle preemption at traffic lights promote bicycle efficiency.

Relatedness needs include the need to belong and to create meaningful social relationships in order to gain acceptance, confirmation, support, understanding, and influence (Alderfer, 1969). Relatedness needs to motivate interacting socially, creating a social identity, and conforming to social norms in order to belong and gain appreciation. Relatedness needs can be satisfied by significant others, expanding social networks, and the community at large, with the strength of relatedness depending on the strength of the social ties and influence. Cycling relatedness needs motivate conforming to cultural cycling norms, taking part in cycling as a group activity, creating a cyclist social identity, and using cycling as a platform for social interaction (Chi et al., 2020; Grayson et al., 2019; Kaplan et al., 2018a, 2018b; Lois et al., 2015).

Growth needs entail a person utilizing their capacity to have an effect on themselves or their environment, enhancing capacity and autonomy, developing new capabilities, and finding the opportunities to realize their full potential (Alderfer, 1969). By definition, the ERG embodies the SDT constructs, which focus on three types of needs: competence, autonomy, and relatedness (Ryan and Deci, 2000). Growth needs trigger normative goal framing because they encompass the development of self-efficacy, autonomy, and self-identity by acting in agreement with normative values, increasing performance, and learning new skills. In interpreting growth needs, Lois et al. (2015), Grayson et al. (2019), and Chi et al. (2020) focused on growth as the effect on the self. Kaplan et al. (2018a) elicited a person's effect on themselves and their environment, self-identity formation, and acting in accordance with environmental values.

Satisfaction

Utilitarian and recreational cycling satisfaction has been explored for children (Westman et al., 2017), adults, and the elderly (Zander et al., 2013) in various countries. Cycling satisfaction is a desirable outcome contributing to feelings of enjoyment, long-term general well-being, and an increase in productivity (Luth et al., 2017; Zander et al., 2013). It also serves as a motivational factor through triggering the formation of cycling attitudes and nurturing the habit formation loop (De Vos et al., 2019; Ingvardson et al., 2020; Rowe et al., 2016). The importance of considering the dual role of satisfaction as both a motivator and a reward is demonstrated in de Kruijf et al. (2019) study, which examined expected versus actual e-bike travel satisfaction. Although they

found a statistically significant difference between expectations and actual satisfaction, the results show that on average, people can reasonably assess their long-term cycling satisfaction. Another important reason to consider cycling satisfaction is the interweave between leisure and work satisfaction (Luth et al., 2017). Both work and cycling satisfaction derive from balanced activity engagement and having a promotion focus; hence, encouraging cycling as a leisure activity can evoke satisfaction in other life domains.

Cycling is a common social practice during childhood encouraged in both bicycle-friendly and car-oriented countries. Yet, most research focuses on the travel satisfaction of adults, with little attention to children's cycling happiness, activation, and positive mood. Westman et al. (2017) reduced the knowledge gap by developing the Satisfaction with Travel for Children scale and applying it to assess the travel quality of children aged 10-15. Children who traveled by bicycle and school bus reported higher travel satisfaction than those who traveled by car. Children who cycled to school also had better mood, with higher levels of valence and activation. Overall, the study found that cycling can improve everyday travel for children.

Mood improvements as a result of cycling are expected due to improved blood circulation and the release of neurotransmitters that trigger the brain's reward system. It is interesting to investigate whether cycling has an effect on the mood of those with clinical mood conditions. While evidence of this is scarce, cycling has recently been identified as a means to improve the well-being and life satisfaction of the elderly, and to alleviate depression symptoms in clinical patients. Leyland et al. (2019) explored the influence of regular bike and e-bike riding on cognitive functioning and well-being. Well-being was measured using three questionnaires: the Psychological Well-Being scale, the Satisfaction in Life scale, and the Positive and Negative Affect scale. During the eight-week trial period, the participants cycled for an average of two hours a week. Regular bike users and e-bike cyclists showed a significant improvement in terms of life satisfaction, mood, and cognitive functioning. Zhao et al. (2017) longitudinal clinical trial results show that long-term bicycle riding helps to relieve depression symptoms among hemodialysis patients. While satisfaction was not measured directly, quality of life and clinical depressive symptoms improved.

While studies have found that cyclists are more satisfied with their commute than other mode users, few have explored the underlying reasons for cycling satisfaction (Willis et al., 2013). Satisfaction is pyramidal in structure, with various layers of psychological depth. Satisfaction in its most immediate form refers to mood change that can derive from both physiological reactions and psychological factors. Satisfaction can derive from external factors such as a pleasant environment and trip characteristics (Willis et al., 2013) and can be a result of the ability of cycling to relieve stress (Avila-Palencia et al., 2017), which is an underlying determinant of satisfaction (Elangovan, 2001). However, satisfaction has much deeper roots in the psychological structure. When looking at motivational goal framing, satisfaction can be described from the perspective of normative, gain, and hedonic goal attainment framing. Delving deeper into the psychological structure, satisfaction derives from meeting existence, relatedness, and growth needs, with the latter satisfied through noticeable improvements in self-concepts. The layers of satisfaction have been revealed in qualitative studies and validated using large samples and rigorous statistical models. Analyzing cycling through the lens of the theory of social practice, Spotswood et al. (2015) postulated that material, meaning, and competences motivate cycling behavior. Their interpretation of material as a means to reproduce daily life, meaning as normative beliefs, and competencies as skills acquirement coincides with the gain and normative goals of the ERG theory of human needs. Thus, the motivational role of satisfaction is also evident in the theory of social practice.

Extrinsic Satisfaction Sources

While there is much knowledge regarding the influence of the built environment on cycling frequency and prevalence, the relationship between the built environment and cycling satisfaction is less explored (Willis et al., 2013). Moreover, evidence from different locations yields some contradictory results, meaning that the results are not readily transferrable across geographical regions.

Infrastructure design and urban design are sources of cycling satisfaction in both cycling-friendly and car-oriented countries. Ho et al. (2015) qualitative results showed that cycling in a pleasant urban environment contributes to enjoyment. Their findings include statements such as "I enjoyed the scenic beauty along the cycling route," which show a direct linkage between the cycling environment and cyclists' sense of joy. Snizek et al. (2013) mapped cyclists' perceived positive and negative experiences along cycling routes in Copenhagen. Regression analysis results showed that cycling satisfaction depends on separated cycling paths, road hierarchy, commercial land use, and the share of green edges along the cycling path. de Kruijf et al. (2019) found that e-bike travel satisfaction in the Netherlands is positively related to green edges, while other characteristics of the built environment, such as aesthetics and street atmosphere, were insignificant. Sharma et al. (2019) performed a regression analysis to find the factors affecting satisfaction with the bicycle roads in Seoul, with a focus on engineering design. Their findings show the effect of engineering design and inducing cycling comfort on the quality of cyclists' experience. They found that satisfaction is related to good condition asphalt, wide cycle lanes, moderate slope, sufficient signage, separation from road traffic, and bicycle parking availability. Through analyzing a cycling infrastructure improvement case study, Skov-Petersen et al. (2017) showed that cyclists are sensitive to engineering improvements in terms of both satisfaction levels and behavioral change. User satisfaction with bike-sharing was also investigated, with the overall level of satisfaction found to be related to bicycle comfort, availability, customer response efficiency, and smartphone compatibility (Maioli et al., 2019).

Willis et al. (2013) explored the relationship between the built environment and the cycling satisfaction of several cyclist types: cycling enthusiasts, exercise-convenience motivated cyclists, active environmentalists, and year-round cyclists. While they did not find a significant difference between "satisfied" and "non-satisfied" cyclists, possibly due to the low variation in the urban

environment, they found that cycling distance is associated with a higher level of satisfaction among cycling enthusiasts. The authors suggested that intrinsic motivators related to economic saving, pleasure, and identity motivate satisfaction. This opened the door to understanding satisfaction through the lens of the normative, gain, and hedonic goal framing theory and through the lens of the theory of human needs.

Intrinsic Satisfaction Sources

Luth et al. (2017) explained cycling satisfaction as the result of being passionate about cycling and having a high promotion focus directed at cycling. Passion arises from the need to satisfy emotional needs, which are manifested through life goals. Looking through the lens of goal attainment (Lindenberg and Steg, 2007), studies show that satisfaction derived from goal attainment varies between recreational and utilitarian cyclists, and between car-oriented and cycling-oriented environments. Rowe et al. (2016) showed that for women recreational cyclists, enjoyment is derived from normative, gain, and hedonic goal attainment. Normative goal attainment seeks to pursue environmental, health, and fitness goals, along with travel independence, control, and autonomy, which give rise to feelings of empowerment. Gain goal framing arises from time and monetary savings, convenience versus other transport modes, increased activity participation, and increased spatial locus of opportunities. Notably, normative and gain goals are interlinked because gain goal attainment can help to attain normative goals. Hedonic feelings arise with sensation seeking, the stimulation of the visual and somatic sensory systems as a result of outdoor cycling in a pleasant environment, and the triggering of fond childhood memories. Rowe et al. (2016) showed that cyclists can articulate the goals attained, attain multiple goals simultaneously, and link goal attainment to enjoyment. Spotswood et al. (2015) suggested differences between the hedonic goal framing of recreational and utility cyclists, while normative and gain goal framing for the two groups are aligned. Spotswood et al. (2015) found that in a car-oriented environment, utilitarian cyclists tend to report less enjoyment and focus either on gain goals (i.e., monetary and time savings) or on normative goal framing (i.e., fitness improvement, sporty and valiant image) due to the stressful car-oriented cycling environment. They also found that while recreational cycling is associated with a sense of competence, utilitarian cycling is associated with bravery and commitment.

If one delves deeper into the psychological structure, cycling satisfaction is rooted in the fulfillment of existence, relatedness, and growth needs. Ingvardson et al. (2020) investigated the role of meeting human needs and its relationship to the travel satisfaction of car, public transport, and bicycle commuters in Denmark. The level of satisfaction of car users and bicycle riders was very similar, with 40% of the respondents indicating the highest level of satisfaction for both modes. The study shows that in a bicycle-oriented country, the bicycle is a competitive alternative to car driving. The findings reveal that while car driving satisfies functional needs and generates positive self-concepts, bicycle riding meets self-efficacy and togetherness, generates positive self-concepts, and triggers travel satisfaction. The analysis verified a statistically significant link between the fulfillment of needs and travel satisfaction. Kaplan et al. (2019a) explored the relationship between cycling self-concepts and mood improvements among cyclists in Australia. They measured happiness, enthusiasm, relaxation, and composure (calmness and focus) using a scale adapted from the profile mood states scale. Taking a domain-specific multidimensional approach, Kaplan et al. (2019a) developed a scale for measuring cycling self-concepts, encompassing four abilities: physical, social, emotional, and contextual. The cycling self-concept scale assessed physical, competence, social, and psychological self-concepts. Physical self-concepts include items that measure appearance and functioning, since the function is a more powerful and enduring self-concept than physical appearance. The physical self-concept scale refers to staying in shape, reaching fitness goals, feeling younger, developing strength, mobility and energy, and improving physical abilities. The competence scale addresses coping with challenges by overcoming topography, weather, and functional difficulties. The scale concerns self-actualization, self-esteem, optimism, and making the best of every situation. The social scale focuses on the perceived improvement in the ability to socialize by expanding the social network, having meaningful conversations, and bonding through a shared activity. The findings show both a direct relationship between cycling and mood improvement and an indirect relationship, with self-concepts as mediators between cycling and mood improvement.

Further Research

Cycling motivation research keeps expanding in new directions and there are important areas to be further explored. Three main research needs are presented.

Cycling socialization. Current studies focus mainly on adult behavioral change. However, current generations are responsible for the travel behavior of future generations. Baslington (2008) showed how travel socialization processes deliver travel behavior from parents to children. Sigurdardottir et al. (2013) showed that children take their parents as role models for cycling choice, influencing their view of themselves as future cyclists or car users. Yet, in-depth analysis of the socialization process has not been conducted. A possible research direction is using the symbolic interaction theory to explain cycling socialization processes. This theory postulates that people validate their self-concepts by regarding themselves from the perspective of others, as reflected through their own perceptions. Kaplan et al. (2019c) validated the theory for adult cyclists, but it has not been applied to explore cycling habit formation among children. Family climate is a powerful force shaping children's behavior through role models, feedback, communication, monitoring, commitment, and limits (Taubman-Ben-Ari and Katz-Ben-Ami, 2013). Currently, there is no research addressing the link between family climate and cycling among children.

Switching to cycling. Most studies focus on cycling as a standalone decision rather than a mode switching decision. The main competitor of cycling is the car, in both car-oriented and bicycle-friendly countries (Ingvardson et al., 2020). The switch from other transport modes to cycling is non-trivial due to difficulties related to individual characteristics, trip attributes, and the urban form. Currently, psychological factors are outside the choice context. A few studies document change or switching behavior (Bird et al., 2018; Kaplan et al., 2018a; Thigpen et al., 2019). Studies internalizing psychological motivation into modal choice using hybrid discrete choice models need to be elaborated so that choice psychology can also be used as an integral part of agent-based transport models. Moreover, according to the trans-theoretical model (Prochaska and DiClemente, 1983), behavioral change requires several stages: pre-contemplation, contemplation, preparation, action, maintenance, and relapse. In the context of cycling choice, these stages translate into awareness, cognitive assessment, motivation formation, preparation, action, maintenance, and switching back to other modes. Currently, only the cognitive assessment and motivation stages are addressed. While loyalty to bike-sharing systems has been investigated (Chen, 2016), the overall change process over time has not been documented. More information is needed regarding the overall change process, its time span, and the most important success factors. Moreover, the maintenance stage and possible relapse to other modes should be explored to expand cycling from a niche market to a common modal choice. Longitudinal studies tracking cycling behavior over time are needed.

Measuring satisfaction. Evaluating satisfaction from self-reports using satisfaction scales is a common practice. A few studies used self-reporting to track cycling satisfaction along cycling routes (Snizek et al., 2013). However, such studies are limited in terms of satisfaction point identification, self-report biases, and continuous satisfaction measurements. Shoval et al. (2018) showed how the emotional dimension of the city experience can be mapped using real-time tracking of emotional arousal (positive or negative) through physiological monitoring. Such monitoring could help in understanding the link between urban form and hedonic reactions to cycling, and how the intensity and length of the hedonic gratification influence habit formation. Satisfaction monitoring using physiological measures could also link cycling well-being with objective measurements of cycling health improvements. This research direction combines data science and psychology and pertains to the next generation of citizen-based science and data visualization.

Definitions

The term “motorcyclist” includes both the rider who is controlling the motorcycle and any passengers who are seated behind (pillion passengers) or in a sidecar or other attachment. However, the definition and scope of the term motorcycle is more contested. The term “powered two-wheeler” (PTW) has been used in European publications to refer to mopeds, scooters, and motorcycles; and commonly includes similar three-wheeled vehicles. Many jurisdictions define mopeds in terms of engine capacity (usually lower than 50 cc) and top speed (often lower than 50 km/h). In general, mopeds and scooters have a “step-through” design and automatic transmission, while motorcycles must be straddled by the rider and have manual transmissions. There is no official definition of a scooter and they are recorded as mopeds or motorcycles in official databases, depending on their engine size and top speed.

The recent growth in sales of e-bikes and e-scooters has blurred the distinction with mopeds and scooters. Up to 60% of e-bikes sold in China (the world’s largest market) are faster and/or heavier than legally allowed (Wei et al., 2013), suggesting that they should be classified as electric mopeds or motorcycles. The “speed e-bikes” in Europe are sometimes regulated as mopeds. New classification systems have emerged in response to the proliferation of new technology. Under the Society of Automotive Engineers (SAE, 2019) new standard - SAE J3194 Taxonomy and classification of powered micromobility devices—a moped would likely be classified as a Mid-Weight Plus, Standard-width, Medium-speed seated scooter (WT4/WD1/SP3/C seated scooter).

Conflicting Perspectives

Motorcyclists and motorcycles polarize community views. PTWs have appeal for transport because of their low cost, high fuel efficiency, comparable speeds to cars, high manoeuvrability, less space needed for parking and ability to weave through traffic jams (Tiwari, 2015). Motorcycling for recreation is attractive as a lifestyle choice because of its image, the thrill of riding, the feeling of freedom, and to impress others (Watson et al., 2007). Yet many people in the general community, and in road safety, see motorcycling as a dangerous pursuit and motorcyclists as risk-takers. These factors are clearly of interest to traffic psychology.

Motorcycles are popular. Between 2013 and 2016, the number of two- and three-wheelers operating in the world increased by 10% and in 10 countries motorcycles make up more than 70% of the vehicle fleet (WHO, 2018). Motorcycles comprise a small minority of registered vehicles in many high income countries (e.g. 3% in the US in 2017, 4.5% in Australia in 2019) but their numbers increased by 57% in the US and 79% in Australia between 2001–05 and 2013–17 (ABS, 2005, 2007; BITRE, 2011, 2020; NCSA, 2019).

Table 1 Inter-relationships between motorcycle type, rider characteristics, purpose and location of riding and crash risk factors and characteristics

<i>Common characteristics</i>	<i>Recreation</i>	<i>Transport</i>	<i>Occupational</i>
Type of motorcycle	Larger or off-road	Often smaller, including mopeds and scooters	Often smaller, including mopeds and scooters
Location	Often rural	Largely urban	Largely urban but some farm use
Type of rider	Older and returning riders	Mixed	Lower income in LMICs
Risk factors	Road related factors (incl. curves), inexperience (incl. returning riders), speeding, drink riding	Driver failure to see, inexperience (esp. braking), filtering, speeding, lack of protective clothing	Nonuse of helmets in LMICs, esp. by passengers, and on farms, overloading, poor maintenance, speeding
Crash characteristics	Single vehicle incl. run-off-road and hit roadside objects, esp. on curves	Multivehicle esp. at intersections	Multivehicle esp. at intersections in urban areas, rollover on farms

Globally, 28% of those killed in road crashes are using motorized two- and three-wheelers. In the WHO South-East Asia and Western Pacific regions, these riders comprise 43% and 36% of all deaths, respectively (WHO, 2018). Despite their lower usage, they comprise 14% of all road crash fatalities in the US (2017; NCSA, 2019), 19% in Great Britain (2019; DfT, 2020c) and 18% in Australia (2019; BITRE, 2020). Along with bicyclists and pedestrians, motorcyclists are often classed as ‘vulnerable road users’: motorcyclists were nearly 27 times more likely to be killed than a car occupant per vehicle mile traveled in the US (NCSA, 2019) and 63 times more likely to be killed than a car occupant per billion passenger miles in Great Britain (2019, DfT, 2020c).

Road safety agencies and police are concerned about the increasing numbers of crashes and fatalities, but transport professionals and the motorcycle industry and enthusiasts point to the declining fatality rate. Indeed, the fatality rate per 10,000 registered motorcycles in the US dropped by 16% (from 6.9 to 5.8) from 2001–05 to 2013–17, while in Australia it dropped by 43% (from 5.5 to 3.1).

Diversity in Motorcycling

There are complex relationships among motorcycle type, rider characteristics, purpose of riding and distance ridden which influences the magnitude and nature of the resulting safety issues. Table 1 attempts to summarize these factors which are then discussed.

Purposes of Riding

Recreational riding is more common than commuter riding in North America, the United Kingdom, Northern Europe and Australasia but the opposite pattern is observed in Southern Europe, and in low- and middle-income countries (LMICs). In many LMICs, motorcycles are the only affordable means of motorized transport and high levels of congestion and inadequate public transport make motorcycles the most practical form of transport (OECD/ITF, 2015). Occupational use of motorcycles is common in some countries for postal deliveries, and in many LMICs motorcycle taxis have become widespread, where customers are transported as pillion passengers.

Motorcycle Types

Purpose of riding influences choice of type of motorcycle. Recreational riding is associated with larger motorcycles which can travel faster and provide more comfort. Smaller motorcycles and scooters are more common for commuter and occupational riding, given that they are less expensive to purchase and operate and more manoeuvrable in dense traffic.

Regulations can also affect choice of motorcycle type. Mopeds are much more common in countries where they are exempt from or are subject to less stringent licensing and registration requirements. In some European countries (e.g. the Netherlands, France), the minimum age for a moped licence is low, so moped use by young riders presents a significant road safety issue (Aare and Holst, 2003). Official estimates of moped numbers are not available in most global documents because they are not required to be registered in some countries.

Blackman and Haworth (2013) reported that the crash rates per registered vehicle were similar for mopeds, scooters and motorcycles, but the moped crash rate per vehicle-kilometer traveled was nearly four times that of motorcycles and larger scooters because the average distance traveled per year by mopeds was much lower. Amongst larger motorcycles, considerable research has focused on the extent to which engine capacity and power-to-weight ratio influence crash risk and severity, given that these characteristics can be regulated in licensing and registration systems. An analysis of Australian motorcycle crashes (Budd et al., 2018) found that crash risk increased with power-to-weight ratio but crash severity was more strongly influenced by engine size.

Super sport and sports types appear to be among the least safe motorcycle types (Budd et al., 2018; Teoh and Campbell, 2010) but comparisons of other types have produced varying results. Comparing the safety of different types of motorcycles is challenging because some types are ridden further per year than others and comparisons based on crashes per registered vehicle may mask higher crash risks per distance traveled. Another challenge in interpreting variations in observed safety among motorcycle types is that the characteristics of their riders differ, and these characteristics likely affect how safely they are ridden.

Riding Locations

Riding for commuting purposes occurs mostly on urban, relatively low-speed roads while recreational riders favor rural, high-speed, winding roads. These rural roads generally have lower in-built safety standards, poor maintenance and little police enforcement which together contribute to the higher crash risk of recreational riding (Haworth et al., 1997; Moskal et al., 2012).

Off-road motorcycle riding occurs for recreation ("dirt bike riding", or "trail bike riding") and agricultural purposes, although All-Terrain Vehicles (ATVs) have increasingly replaced motorcycles for this purpose. The amount of off-road riding is likely to be significant in countries because where off-road motorcycles comprise a large segment of motorcycles sold (e.g. US: 21% in 2019; Statista, 2020 and Australia: 38% in 2019; FCAI, 2020). In Australia, similar numbers of motorcyclists are hospitalised following on- and off-road incidents (AIHW, 2018).

Rider Demographics

Younger, older and returning riders

In many high-income countries, the growth in recreational riding has largely been among men who are middle aged and over. A US survey (MIC, 2019) reported that the median age of motorcycle owners in 2018 was 50, rising from 45 in 2012. Budd et al. (2018) reported that in Victoria, Australia, the number of motorcycle licences issued to older riders grew by almost 300% and the learner permits doubled over the period 2006–15. Older motorcyclists were more likely ride on open roads which at higher speeds makes them more vulnerable. The proportion of injury crashes involving riders aged 60 years and over doubled to 7% from 2005 to 2014 and these riders had poorer injury outcomes.

Older riders comprise continuing, new and returning riders, with the proportions depending on the definition used (Haworth et al., 2013). While findings vary, the crash risk of returning riders appears to be elevated in terms of distance ridden, but not per licence held. An elevated crash risk could result from a deterioration in motorcycle handling skills due to lack of practice, changes in motorcycle design and performance over time leading to unfamiliarity with the motorcycle, or rider attitudes and behaviors (Mulvihill and Symmons, 2010).

Despite the growth in numbers of older and returning riders and their contribution to crash numbers, crash rates remain highest for the youngest riders who, while numerically small, are inexperienced with both riding and the traffic system, and share the risk-taking characteristics of their peers.

Women who ride

Across high-income countries, a large majority of motorcyclists are male, although relatively more women ride scooters. The number of female motorcycle riders appears to be increasing in the US, with surveys showing an increase in the proportion of motorcycle owners who were women from 10% in 2009 to 19% in 2018 (MIC, 2018). In contrast, the representation of women among candidates passing the practical motorcycle tests in the UK has remained between 7.5 and 9.5% since 2009/10 (DfT, 2020a,b). Relatively little is known about the characteristics of women who ride, although a media release from a UK insurer (The Bike Insurer, 2018) stated that 8% of insurance quotes in 2017–18 were provided to women, whose average age was 37. The most common engine size was 125 cc, and average annual mileage was 3,000 miles (4800 km). Little information is available to compare the safety of male and female riders, although women appear to be more interested in safety-focused motorcycle training than men.

Factors Contributing to Motorcycle Crashes

The psychosocial factors contributing to motorcycle crashes include failure by drivers to see motorcycles, rider inexperience, and risky attitudes and behaviors. In addition, because they have only two wheels, motorcycles are much more sensitive to deficits in road design and maintenance and the unprotected nature of riders mean that collisions with roadside furniture and other objects contributes significantly to the severity of injuries in single-vehicle crashes. A more detailed summary of the factors contributing to motorcycle crashes is provided in OECD/ITF (2015).

Failure by Drivers to See Motorcycles

Many motorcycle crashes occur because of errors or violations by drivers of other motor vehicles. For example, almost half of the fatal motorcycle crashes in the US in 2017 involved collisions with other motor vehicles and in 42% of the two-vehicle crashes, the other vehicle was turning left across the path of the motorcycle which was going straight (NCSA, 2019). In many crashes of this type, the other driver claims to have not seen the motorcyclist. Drivers' failure to see motorcyclists results from poor sensory (or physical conspicuity) because the motorcycle is a small visual target and poor cognitive conspicuity because drivers do not expect to see motorcycles in countries where motorcycles make up a small proportion of the traffic stream.

Inexperience

Like novice drivers, inexperienced riders have higher crash risks, possibly related to their poorer braking skills or less developed hazard perception. Some inexperienced riders are unlicensed, inflating the representation of inexperienced riders in crashes. In the US in 2017, 29% of motorcycle riders in fatal crashes did not have valid licences (NCSA, 2019). In Australia, Budd et al. (2018) found that the odds of a more severe injury crash outcome were 25% higher if the rider was unlicensed, but it is unclear whether this reflects a true increase or unwillingness to report less severe crashes.

However, unlike drivers, many riders do not ride much and so remain inexperienced. For example, in the US in 2017, motorcycles traveled only 2312 miles per year on average. Motorcyclists who ride less have relatively higher crash risks per unit of distance traveled than those who ride more often (Harrison and Christie, 2005). Riding a new or borrowed is also associated with increased crash risk (Haworth et al., 1997).

Risky Attitudes and Behaviors

Psychosocial factors have largely been studied in relation to recreational riding, because most research has been undertaken in high-income countries where recreational riding is more common. However, the psychological underpinnings of observed behaviors may differ among countries. In some LMICs, nonwearing of helmets may reflect lack of laws and enforcement, and potentially tropical climates, rather than deliberate risk-taking. Similarly, nonwearing helmets may be a much stronger indication of risky attitudes in Australia (where nonhelmet use on public roads is rare) than in some of the US States where helmet use is not compulsory.

Motorcycling shares some psychosocial aspects with other forms of mobility, such as attribution and calibration errors and influences from peers.

The poor safety record of motorcycling may partly result from it being attractive to people with an increased propensity for risk taking (Horswill and Helman, 2003; Tunncliffe et al., 2012). In addition, some motorcycling research (e.g. Tunncliffe et al., 2012) suggests that the influence of “people I ride with” may be particularly important and that some risky behaviors may be motivated by a desire to keep up with the group.

Speeding is more common in motorcycle than car crashes, with 32% of motorcycle riders in fatal crashes being speeding versus 18% of drivers in the US in 2017 (NCSA, 2019). Motorcycles often travel faster than other vehicles in urban areas, which can result in crashes because they are traveling faster through intersections than other road users expect (OECD/ITF, 2015).

While alcohol is clearly incompatible with safe motorcycling, the extent of its involvement in motorcycle crashes differs widely across countries. In some LMICs where alcohol consumption rates are very high and motorcycles are the most common form of transport, a large proportion of crashes involve alcohol. In the US in 2017, 28% of motorcycle riders killed in motor vehicle crashes had an illegal level of alcohol (BAC 0.08 g/dL or higher) and another 7% had lower levels of alcohol (NCSA, 2019). Alcohol is generally more prevalent in motorcycle riders than car drivers in fatal crashes in the US but not in some other countries (e.g., Australia, France, Sweden are mentioned in OECD/ITF, 2015). In common with other vehicles, alcohol is more common in single- than multi-vehicle motorcycle crashes, and in fatal crashes than injury crashes.

Risky behaviors tend to co-occur which makes it difficult to assess the relative contribution of each factor to crash risk and severity (see review by Theofilatos and Yannis, 2015). For example, a host of studies in high-income countries have found that not wearing a helmet and drink riding co-occur, often also among males who are riding for recreation. Speeding and being unlicensed also tend to be part of this constellation of risky behaviors.

There is controversy regarding whether lane filtering is risky and its prevalence and legal status varies among jurisdictions (Clabaux et al., 2017). Many riders maintain that filtering reduces their risk of being hit from behind by a car, or that it prevents their motorcycle's engine overheating in slow-moving traffic. A series of French studies (Clabaux et al., 2017, 2019) demonstrated that filtering on urban roads increased crash risk four-fold, that the risk of hitting pedestrians in city centers was more than five times higher for filtering than for non-filtering motorcycles, and that filtering more than doubled crash risk on urban freeways. The increased risk may relate to filtering riders being less detectable or predictable by drivers, or other aspects of the risky behavior of these riders (Clabaux et al., 2017).

Riding without adequate protective clothing can increase crash severity and is an objectively risky behavior but it does not appear to correlate with other risky behaviors and attitudes (de Rome et al., 2011).

Measures to Improve Motorcycle Safety

Many of the general road safety measures (e.g. speed limits that align with infrastructure safety, reduction in impaired driving) also improve motorcycle safety, particularly to the extent that these measures contribute to drivers of larger vehicles being less likely to collide with motorcycles. Improvements to the road environment may be the most effective measures prevent or reduce the severity of crashes resulting from the factors outlined in the previous section. For example, dedicated turning lanes and installation of traffic signals (or changes to the phasing of existing signals) can reduce turn-in-front-of crashes that occur because turning drivers fail to see motorcycles. Improvements to skid resistance and widening of shoulders on curves can prevent run-off-road crashes on curves where motorcycles are deliberately or inadvertently speeding.

Rider Training and Licensing

Licensing requirements vary among jurisdictions and often depend on how the vehicle is classified. Internationally, the approach to moped licensing varies from no training or licence requirement to moped riders requiring a motorcycle licence. In some countries, the licensing age for mopeds is lower than for cars and motorcycles, and moped use is seen as an introduction to motorized independent mobility.

Vehicle-based restrictions are common in licensing systems, such as restricting the engine capacity and/or power-to-weight ratio of motorcycles that novices are allowed to ride, or requiring additional training and/or testing to allow access to more powerful motorcycles. While some of these requirements may have reduced motorcycle crashes by making motorcycling less attractive, their

effectiveness in reducing crash risk among those who ride has not been clearly demonstrated, possibly because confounding effects of age, type of motorcycle and distance ridden (Budd et al., 2018).

Attempts have been made to adapt graduated licensing schemes used for car licensing to motorcycle licensing but the differences in age and experience profiles between novice drivers and novice riders, the impracticality of supervision and the potential for slow accumulation of experience mean that simple adaptations may not be appropriate (Haworth and Rowden, 2010).

Evaluations of the effectiveness of training in improving rider safety have been inconclusive (e.g. Kardamanidis et al., 2010). Many of the same issues arise as in training as for car drivers—skills-based training potentially leading to over-confidence and greater likelihood to indulge in risky behaviors. There is a trend to encourage training to focus more on modifying rider attitudes and higher-order cognitive skills such as hazard perception but to motivate riders and trainers there is a need to include these components in licence testing. Post-licence training is undertaken by relatively few riders and often focuses on further development of vehicle control skills, which can result in increased risk-taking. Many authorities promote voluntary refresher training for returning riders but this is completed by relatively few returning riders.

Enforcement of Road Rules

Enforcement of road rules to deter illegal behaviors such as speeding is generally less effective for motorcyclists than other road users. Motorcycles can accelerate quickly, travel at high speeds and filter through traffic, making it difficult for police (in cars) to safely apprehend some high-risk riders. Difficulties in identifying motorcycle licence plates using camera-based (electronic) speed enforcement may be contributing to riders being less deterred from speeding in some jurisdictions. Additionally, there can be a mismatch between allocation of enforcement resources and motorcycle use. For example, most motorcycle riding occurs in daytime but most alcohol enforcement occurs at night to follow the drinking patterns of car drivers. Similarly, a lot of speeding by motorcycles occurs on rural roads which traditionally have lower levels of police enforcement because of their lower traffic volumes.

Improving Conspicuity

Requirements for hard-wiring motorcycle headlamps so that they are on even in daytime have reduced the number of multi-vehicle motorcycle crashes in a range of countries (see OECD/ITF, 2015). There is debate regarding whether the introduction of similar requirements for other vehicles has reduced the effectiveness of this measure for motorcycles. The European 2BESAFE project developed and tested a range of alternative headlamp configurations for motorcycles and identified a T-shaped arrangement was most effective.

There is some dispute regarding whether wearing brighter clothing improves the daytime detectability of motorcycles. Experimental studies have suggested that contrast with the background may be more important than brightness.

Attempts to increase drivers' expectancy of motorcyclists have shown only limited and short-term success (Hosking et al., 2007).

Helmets and Protective Clothing

Correct helmet use is associated with a 42% reduction in the risk of fatal injuries and a 69% reduction in the risk of head injuries to motorcyclists (Liu et al., 2008). For this reason, the focus of international efforts has been on increasing helmet use, particularly by enforcement of legislation that requires wearing of helmets that comply with performance standards (WHO, 2018).

Use of effective protective clothing can reduce the severity of non-fatal injuries to motorcyclists in crashes (de Rome et al., 2011). However, the protective performance of garments varies dramatically and riders may not be convinced of the protective value of what can be expensive items. To address this, various approaches have been developed to test protective clothing and/or provide information to consumers (de Rome, 2018).

Safer Motorcycles

Most of the effort in improving the safety of motorcycles has focused on active safety systems which prevent crashes, although development of passive systems such as motorcycle airbags has received some attention (see OECD/ITF, 2015). The effectiveness of antilock braking systems (ABS) has been identified in a range of studies (summarized by Savino et al., 2020). In a recent review, Savino et al. (2020) identified the following active safety systems for PTWs: antilock braking system, autonomous emergency braking, collision avoidance, intersection support, intelligent transportation systems, curve warning, human machine interface systems, stability control, traction control, and vision assistance. They noted that these systems are at different levels of development and there is a need for studies to examine the combined safety benefit of more than one technology.

One of the challenges faced continues to be rider unwillingness to adopt some new technologies, particularly those which reduce or limit rider control of the motorcycle (Beanland et al., 2013). Another factor limiting acceptance is affordability, particularly in LMICs and for lower-priced PTWs.

The Future of Motorcycling

Given increasing levels of urbanization and traffic congestion, the demand for motorcycles for transport is expected to increase. There has been a tendency to move from PTWs to cars in some LMICs as incomes increase, but congestion levels may result in owning both a car and a motorcycle and using them for different purposes (Eccarius and Liu, 2020). Bans on petrol motorcycles and tighter emission controls are expected to continue, leading to an expansion in the use of electric motorcycles (Eccarius and Liu, 2020). New vehicle categories may replace PTWs for short urban trips, with emerging evidence that standing electric scooters may be replacing mopeds in some environments. As part of the move towards a shared mobility, dockless motorcycle sharing schemes have begun in

Europe, largely using battery electric, fully automatic scooters. These schemes may play a role in future Mobility-as-a-Service (MaaS) systems (Eccarius and Liu, 2020). For recreation, 'time share' of motorcycles is growing in the US. While autonomous motorcycles are conceptually possible, rider demand may be low.

What is Drivers' Hazard Perception Skill and Why is it Considered Important?

Those drivers who are better able to predict dangerous situations on the road ahead tend to have fewer crashes than others. This skill has been referred to as *hazard perception*, and it has been a focus of research for over 50 years because of the potential opportunities it offers for both predicting and reducing drivers' crash risk (Horswill, 2016a). Studies have linked hazard perception skill to crash involvement, both retrospectively (Boufous et al., 2011; Cheng et al., 2011; Congdon, 1999; McKenna and Horswill, 1999; Quimby et al., 1986; Tüské et al., 2019) and prospectively (Horswill et al., 2015b; Wells et al., 2008). For instance, Horswill et al. (2015b) found that drivers who initially failed a test of hazard perception used for driver licensing had 25% more crashes during the year following the test than those who passed the first time (excluding parking or reversing incidents, or crashes when the driver's vehicle was stationary). Hazard perception has been found to be associated with crash involvement across the life span, including in samples of novice drivers (Horswill et al., 2015b), drivers aged over 65 years (Horswill et al., 2010a), and cross-age fleet driver samples (Darby et al., 2009).

Hazard perception skill has also been linked with other important crash predictors. For instance, distractions of various kinds have been shown to reduce hazard perception performance among both novice and experienced drivers (Borowsky et al., 2014, 2015, Horswill and McKenna, 1999; Savage et al., 2013). Sleepiness also significantly impacts hazard perception skill (Hamid et al., 2014) in both novice and experienced drivers (Smith et al., 2009), although it has a greater effect on novice drivers. With regards to speeding, drivers with better hazard perception have been found to drive slower (Grayson et al., 2003) and drivers trained in hazard perception tend to choose slower speeds than untrained drivers (McKenna et al., 2006). Alcohol consumption has also been found to impair hazard perception performance (Deery and Love, 1996; West et al., 1993).

This body of evidence has led to the suggestion that problems with hazard perception are implicated in causing a significant proportion of crashes (Horswill, 2016b) in the sense that, when a driver crashes due to driving too fast or being distracted, fatigued, or drunk, the crash may be attributable on some level to a failure of hazard perception. For instance, the crash may have occurred because the driver's judgement was impaired (e.g., by alcohol, distraction, or sleepiness) to the extent that they failed to notice a hazard sufficiently early. Similarly, drivers who fail to recognize a potential hazard on the road ahead might be more willing to drive faster than is appropriate in that situation.

How can Hazard Perception Skill be Measured?

Hazard perception is usually measured using a computer-based *hazard perception test* in which drivers view video footage (or computer-generated images) of traffic situations and make a timed response when they predict that a potentially dangerous situation is developing (Horswill, 2016b; see Fig. 1). Computer-based tests are generally favored over on-road measurement of hazard perception performance for a number of reasons, including the following (see Horswill, 2016b). First, high-risk events are too infrequent in real driving to allow drivers' responses to be meaningfully assessed during a single typical journey. Second, measuring when a driver anticipates a hazard is difficult in real driving because this might occur sometime before they have to act. Third, it is difficult to standardize assessment in real driving as no two drivers will encounter exactly the same set of traffic situations. Fourth, there are ethical issues involved in deliberately exposing drivers to hazardous situations for testing purposes.

To give one example of a computer-based hazard perception assessment, the test currently used for driver licensing in Queensland, Australia (Wetton et al., 2011) involves test-takers viewing a series of traffic clips shot from a driver's perspective. Test-takers use a computer mouse to click on any other road user (i.e., vehicle, cyclist, or pedestrian) that is likely to become involved in a traffic conflict with their vehicle (i.e., the car containing the camera). A *traffic conflict* is defined as a situation in which the camera car needs to take action by slowing down or changing course to prevent a crash. The time taken to respond to each traffic conflict is

Figure 1 Screenshot from a hazard perception test video, showing a view of the road shot from the driver's perspective (Hill et al., 2019).

averaged over all conflicts to provide an overall score. Evidence indicates that scores from this type of hazard perception test (including similar tests that employ a simple button-press response mode) reflect real driving behavior, even though taking the test does not involve real driving. For example, hazard perception test scores predict on-road driver performance ratings (Grayson et al., 2003; Mills et al., 1998; Ross et al., 2013; Wood et al., 2013), as well as crash involvement (Horswill et al., 2015b), and are able to distinguish high-risk driver groups (young novices) from lower-risk groups (mid-age experienced drivers) (Borowsky et al., 2009, 2010; Horswill et al., 2008; Manley et al., 2020; McKenna and Crick, 1991; Smith et al., 2009; Wallis and Horswill, 2007; Wetton et al., 2010).

It is worth noting that it is not a trivial exercise to create an effective and valid hazard perception test. For instance, an early prototype of the UK licensing hazard perception test failed to predict crash risk and failed to distinguish novice and experienced drivers (Grayson and Sexton, 2002), prompting a significant redesign. Researchers have argued that this is because only certain types of hazard scenes can be used for measuring this skill (Crundall et al., 2012; Grayson and Sexton, 2002; Sagberg and Bjørnskau, 2006; Wetton et al., 2011). The consensus seems to be that a scene that is appropriate for a hazard perception test needs to involve sufficiently subtle anticipatory cues to allow drivers who are good at hazard perception to display their superiority over those who are not as good. Tests containing hazards that, under high-vigilance test conditions, are equally obvious to all drivers (e.g., where test developers have primarily chosen hazards because they appear to represent high-frequency crash types) have no power to tell apart good and bad drivers, which is the fundamental objective of the test (Horswill, 2016b).

Another method for measuring hazard perception skill (known as a *hazard prediction test*) involves showing drivers clips of potentially dangerous traffic incidents, stopping each clip just before the incident, and then asking the test-taker to predict what will happen next (Jackson et al., 2009). The quality of drivers' predictions has been found to be associated with self-reported crash involvement (Horswill et al., 2020), as well as distinguishing high-risk (young novices) and lower-risk (older experienced drivers) groups (Crundall, 2016; Horswill et al., 2020; Lim et al., 2014; Ventsislavova and Crundall, 2018; Ventsislavova et al., 2019).

Eye tracking has also been used to measure hazard perception skill, by determining whether and when drivers look at locations in a traffic scene relevant to anticipating hazards. For example, Pradhan et al. (2009) tracked drivers' gaze during real driving and examined fixations on stationary areas of the road environment that a skilled driver ought to be monitoring (e.g., a side road where the view into that road is obscured). Similar techniques have been used with drivers viewing video or computer-generated images of traffic scenes (Taylor et al., 2013). One advantage of this approach is that drivers do not have to perform any task that is not part of normal driving (e.g., generating predictions out loud or pressing a button) to obtain a score. However, one criticism of this technique is that it assumes that drivers are always paying attention to what they are looking at, which is known not to be the case. Also, while novice/experienced differences have been found for eye-scanning patterns (Underwood et al., 2003), no direct association with crash involvement has yet been shown for scores derived from eye-tracking data.

Other researchers have created tests of hazard perception in which test-takers drive a simulated vehicle through a virtual reality traffic environment. One method of scoring hazard perception skill in this type of assessment has been to measure vehicle speed

during the approach to a hazard, where drivers with superior hazard perception would be expected to slow earlier (Crundall et al., 2012). An advantage of this approach is that, unlike other methods, it indicates whether drivers are capable of taking appropriate action once they have anticipated a hazard. Also, the very act of having to control a vehicle is likely to influence visual scanning behavior, such that drivers' gaze patterns may be more representative of real driving than in tests where the driver is instead watching a video. On the other hand, giving test-takers control over the vehicle may change the nature of the hazards from driver-to-driver, undermining the comparability of test scores across participants (e.g., if a driver is driving more slowly than others, then they may not need to anticipate hazards as early to maintain the same level of safety). A further issue is that the computer-generated imagery typically used in these simulators is considerably less realistic than the equivalent filmed scene. If drivers are aware that a situation is fake, then this may change their attitudes and behaviors toward any hazards.

As previously noted, on-road measures of hazard perception are generally considered more problematic than computer-based measures for most purposes. However, some researchers (Pradhan et al., 2009) have used eye-tracking to measure hazard perception skill during real driving, as discussed above. Others have set up staged hazards on closed-circuit tracks (Lee et al., 2008; Wood, 2002) and measured performance using indicators such as the time that drivers first fixated the hazard and whether they behaved appropriately on the approach to the hazard. This method has yielded novice/experienced driver differences (Lee et al., 2008). Driving instructor ratings of hazard perception during a single journey have also been used (Wood et al., 2013), though this technique has the additional complication that the rater is not blind to the driver's appearance, which could potentially influence their judgement (e.g., they may be biased toward giving young-looking people worse ratings because they are aware that younger drivers tend to have poorer hazard perception skill).

Other methods of measuring hazard perception have involved static traffic images (Pradhan et al., 2009; Scialfa et al., 2013; Tüské et al., 2019), schematic plans of traffic situations (Pollatsek et al., 2006), and retrospective judgements of traffic clips (Renge et al., 2005; Vlakveld, 2014).

How does Hazard Perception Change across the Life Span?

Hazard perception varies systematically across the life span, with younger drivers having a lower level of competence than mid-age drivers (Horswill, 2016a). This age-related difference is highly confounded with driving experience, which it presumably reflects, and is in turn reflected in the relative crash risk of these two groups. However, hazard perception performance peaks at around 55 years (Quimby and Watts, 1981). By the time drivers reach 75 years of age, the decline in their hazard perception skill compared with mid-age drivers becomes significant (Horswill et al., 2009).

These changes in hazard perception performance across the life span have been conceptualized in terms of drivers' mental representations of the traffic environment (Horswill, 2016a). Learners are thought to start out with a relatively impoverished understanding of the road environment, whereby they are more likely to simply react to dangerous events rather than proactively predicting them (Horswill and McKenna, 2004). As they gain experience, their mental representation of the traffic environment becomes gradually more sophisticated. In practical terms, this means that more experienced drivers have a better understanding of the subtleties of where and when potential hazards might arise. This allows them to make more accurate predictions as to what might happen next in any given situation, allowing them to anticipate where other road users might appear from, how they might behave, and where they might go (Horswill, 2016c). This ability to predict dangerous events earlier is thought to lead to safer behavior because it provides drivers with more time to deal with any dangerous situations that might arise, and also allows them to take action to reduce the risk of potential hazards before they transpire (e.g., by slowing down when approaching a location where another road user could potentially emerge without warning). This mechanism reflects the concept of hazard perception as situation awareness on the road (Horswill and McKenna, 2004), where drivers with poor hazard perception have poorer perception and comprehension of what is happening around them and are consequently less able to predict what might happen next.

As drivers enter the later stages of life, new problems arise. Due to declines in cognitive capacities, older drivers may not be able to process all of the information required to feed their ongoing dynamic understanding of the road environment as effectively as before. Also, older drivers may find it more challenging to perceive certain stimuli, due to deficits in their useful field of view (i.e., they are less likely to notice stimuli that appear in peripheral vision) and reduced contrast sensitivity (i.e., lower contrast objects become harder to discern). In addition, gradual age-related declines in reaction time, which begin in the mid-20s (Thompson et al., 2014), eventually progress beyond the point where driving experience can compensate (Horswill et al., 2008).

How can Hazard Perception Skill be Improved?

Given that hazard perception appears to be an important skill for crash risk, and some drivers are considerably more skilled than others, one potential strategy for reducing crashes is to improve the hazard perception skill of those who have not reached an optimal standard. However, a potential problem with this approach is that driver training in general has not been found to be a reliable method of decreasing crash risk (Beanland et al., 2013). In fact, in some cases, driver training has been shown to increase crash involvement (Mayhew et al., 1998). One explanation for these failures is the effect of training on driver confidence. It has been suggested that, while training may indeed increase drivers' skills, it simultaneously increases their confidence in those skills (Gregersen, 1996). Increased confidence has been linked to increased risk-taking (Horswill et al., 2004), as drivers believe their

improved competence enables them to cope better with dangerous situations. This in turn negates the safety benefit of their improved skills. In other words, it is not a foregone conclusion that improving hazard perception skill via training will automatically lead to reductions in crash risk.

Fortunately, the available evidence suggests that hazard perception training can improve drivers' hazard perception skill without increasing their confidence or their propensity to drive more dangerously. In terms of raising skill levels, hazard perception training has been found to improve hazard perception test scores not only for novice drivers (Wetton et al., 2013) whose mental representations of the traffic environment might be underdeveloped, but also for older drivers whose hazard perception may have declined due to factors not related to lack of experience, such as deteriorating cognition, vision, and reaction times (Horswill et al., 2010b, 2015a). In fact, even mid-age experienced drivers have been found to benefit from hazard perception training (Horswill et al., 2013b). In addition, hazard perception training has been found not to increase drivers' self-ratings of their overall driving skill or their hazard perception skill (Horswill et al., 2013b), suggesting that any skill improvements are unlikely to be neutralized by accompanying increases in risk-taking. There is even some evidence that hazard perception training can actually lead to *decreases* in risk-taking intentions (McKenna et al., 2006).

The underlying goal of most hazard perception training interventions (either implicitly or explicitly) is to give trainees greater insight into the expert driver's mindset and their more sophisticated mental model of the traffic environment (Horswill, 2016c). It has been suggested that this approach prevents increases in self-confidence because trainees generally receive repeated feedback indicating that they are noticing far less than would an expert. Increases in risk-taking may also be prevented because drivers with improved hazard perception become more aware of the dangers facing them. In addition, increased risk-taking usually makes the act of perceiving hazards more difficult (e.g., faster drivers have less time to notice hazards; tailgating drivers' view of hazards may be blocked by the vehicle in front), and this is likely to be more apparent to an individual who is actively searching for sources of risk.

A number of different training techniques have been found to improve hazard perception skill. Perhaps the most well-established of these is the use of commentary drives (Åbele et al., 2018, 2019; Cantwell et al., 2013; Crundall et al., 2010; Isler et al., 2009, 2011; McKenna et al., 2006; Young et al., 2017). This typically involves the trainee being asked to generate a running verbal commentary either during real driving or while watching a video shot from the perspective of a driver. The trainee is asked to verbalize what they are looking at, and the dangers they are anticipating. They are then given feedback on the quality of their commentary. For example, in a video-based training exercise, they might watch the same footage overdubbed with an expert driver's commentary to compare with their own attempt, before repeating the process with a new clip. This is designed to provide trainees with insight into the expert driver's mental representation of driving. Commentary drive training has been found to improve response times in computer-based hazard perception tests in a number of studies (Isler et al., 2009; McKenna et al., 2006; Wetton et al., 2013). It has also been found to lead to behavioral changes in a driving simulator, including reduced crash rates, earlier speed decreases when approaching hazards, and earlier braking (Crundall et al., 2010).

Another method of training hazard perception involves prompting drivers where to direct their attention while viewing videos, photos, or computer-generated images of traffic (Agrawal et al., 2018; Pradhan et al., 2009; Yamani et al., 2014). This approach is underpinned by the finding that novice drivers have different visual scanning patterns from experienced drivers (Crundall and Underwood, 1998). For instance, they are less likely to look at locations in the traffic environment that ought to be monitored in case hazards develop (Fisher et al., 2006). To give one example, the first version of the "Risk Awareness and Anticipation Training" (RAPT) system, developed in the US (Pollatsek et al., 2006), involved asking trainees to position markers on a bird's eye schematic view of a driving situation to indicate where hidden (from the perspective of a given vehicle) road users might be located. Trainees were also asked to indicate the locations that the driver of the target vehicle should be monitoring in anticipation of potential hidden road users emerging in a way that might cause a hazard. In a subsequent driving simulator journey, trained participants were found to monitor relevant locations to a greater extent than untrained participants. A later version of RAPT involved showing trainees a series of driver-perspective still images depicting a developing road scene, and asking them to indicate where they ought to be monitoring. Trainees' learnings were found to translate into more effective monitoring of key locations on the road ahead during real driving (Pradhan et al., 2009).

The hazard prediction test method described earlier (in which a clip of traffic cuts to black, and the driver is asked to predict what could happen next) has also been used for training. In the training exercise version (McKenna and Crick, 1997; Poulsen et al., 2010; Wetton et al., 2013), the driver is provided with feedback on their predictions (e.g., they are shown an expert driver's predictions and also see what actually happened after the cut-point). This training approach has been associated with improved hazard perception test scores, both in isolation (Wetton et al., 2013) and in combination with other strategies (Horswill et al., 2013b, Poulsen et al., 2010). One version of this technique, called "HazardTouch" (Shimazaki et al., 2017) involved trainees watching videos of real crashes. This resulted in trained drivers fixating earlier on the edges of blind spots while watching videos of driving and checking those locations more frequently than controls. Trainees also selected slower speeds before intersections during a real-world drive, as well as checking the intersections more frequently and for longer as they passed them.

A key factor for effective skill acquisition that is lacking in everyday driving is high quality and unambiguous performance feedback (Horswill et al., 2017). Given that the average driver only crashes once every ten years (Evans, 1991), it can be argued that, for the vast majority of their driving time, drivers are receiving feedback that their driving is good (in the sense that they are mostly avoiding crashes). This is consistent with the finding that most drivers rate their own driving as better than that of the typical driver (Svenson, 1981), where such ratings have consistently been found to have close-to-zero correlations with objective performance measures (Horswill et al., 2013a). That is, drivers have little insight into their own driving skill. In contrast, most other skilled tasks, such as sports or musicianship, involve rather more frequent performance feedback. It has been argued that effective improvement of

skills can only occur in the presence of meaningful feedback (Ericsson and Poole, 2016) and that this explains why drivers typically take decades to reach their peak in hazard perception. Horswill et al. (2017) created a training exercise designed to address this issue more directly than other hazard perception training methods. It involved drivers responding to clips from a mouse-click response-time hazard perception test, and then being given high quality feedback on their performance. The feedback involved viewing another version of each clip, which had been annotated with crosshairs showing the location and timing of their own response, that of an expert driver, and that of an average driver (Horswill et al., 2017). Trainees were also shown a graph comparing their performance with these other driver groups. This intervention was found to improve response times in a subsequent hazard perception test.

Repetition learning using hazard clips has also been found to be effective in improving hazard perception skill. Kahana-Levy et al. (2019) presented a series of traffic clips to trainees, repeating each clip containing a hazard three times, separated by other clips. They found that drivers fixated hazards earlier when subsequently shown new clips (see also Meir et al., 2014).

However, not all attempts at training hazard perception skill have been successful. One method found to be ineffective is classroom instruction (McKenna and Crick, 1997; Meir et al., 2014), which is of note given its ubiquity as a training method in general.

One limitation of the hazard perception training literature to date is that most interventions have typically only been evaluated using short-term follow ups, ranging from immediately after the training has been completed to a week. For training to reduce crash risk, effects need to last considerably longer than this. However, the limited longer-term research that has been conducted has yielded promising results. For example, Chapman et al. (2002) reported significant learning retention between 3 and 6 months following hazard perception training, while Horswill et al. (2015a) reported no significant decay in performance improvements after three months.

The Impact on Crash Risk of Introducing Hazard Perception Testing and Training

As described above, we have evidence that hazard perception test scores are linked with crash involvement, and we have evidence that hazard perception training improves hazard perception test scores and affects behaviors associated with crash involvement. However, it does not necessarily follow from this that introducing hazard perception testing into driver licensing procedures, or making hazard perception training available, will translate into crash reductions. Nevertheless, the admittedly limited evidence that does address these crash effects shows promise. First, in some European countries, "new paradigm" driver education programs have been introduced, which have a substantial focus on hazard perception (Washington et al., 2011). These programs have been associated with reductions in crash risk, albeit with some methodological caveats (Washington et al., 2011). Second, there is one randomized control trial in the literature examining hazard perception training effects on crash rates (Thomas et al., 2016). This involved a 10-min computer-based training intervention, based on the RAPT program described earlier (Pradhan et al., 2009). While the sample in this study was arguably under-powered, the intervention nonetheless produced a 25% reduction in crashes for male participants during the following year (albeit no reduction for females). Third, the introduction of a hazard perception test into the UK driver licensing system is estimated to have reduced non-low-speed public road crashes by 11.3% for drivers during the year after they have taken the test (Wells et al., 2008). This equates to the prevention of nearly 10,000 crashes per year. While more research to verify these outcomes would be desirable, they nonetheless suggest that measuring and manipulating drivers' hazard perception skill is a viable strategy for improving road safety.

Introduction

Driver education and training are among the earliest and most universal behavioral countermeasures to road crashes. This particularly applies when first learning to drive a car-type vehicle and becoming an independently licensed driver, which is the focus of this article. Originally, such efforts centered on road rules and training of basic skills relating to vehicle handling and maneuvering in traffic in preparation for licensure. Over recent decades, however, there has been a considerable shift in expected outcomes, now also aiming for safer drivers post-licensure; with casualty crashes peaking early in this transition period ([Senserrick and Mitsopoulos-Rubens, 2013](#)).

In this context, current wisdom generally dictates that such efforts are ineffective. That is, the ways in which societies generally educate and train new drivers for licensure do not sufficiently protect them. Certainly, the latter is true. However, if we look closer at the literature, including more recent advances and emerging trends, it could be argued that true wisdom is still lacking. Recent high-quality evaluations of high-quality programs are scant. Approaches that we know are ineffective are popular and prevail, while more nuanced initiatives often require intensive efforts and funding for wider implementation and more compelling evaluation, and do not advance. In this article, we acknowledge this body of literature, but seek to highlight promising research and needs for new directions as the vehicles we drive and the ways in which we travel are progressively being transformed.

Before we elaborate, we acknowledge that much of the research specific to this review has been undertaken in countries in which this transition to independent driving predominantly occurs in the first years following the minimum licensing age. This includes Australia, where the authors are based, and as such this context contributes to the perspectives discussed in this article. Therefore, our focus commonly relates to young drivers, with this term implying a broad age range, in keeping with the United Nations definition of youth as ages 15–24 years. Roles for parents are also sometimes highlighted as relevant to this age group. We use the term driver education holistically, to refer to efforts to increase any driving-related knowledge, and driver training more narrowly, specific to driving skill attainment.

Common Approaches to Novice Driver Education and Training

Best practices in novice driver safety are structured around graduated licensing systems ([Mayhew et al., 2014](#)), that is, systems that progress the novice through various license stages of increasing risk as more driving experience or maturity are gained. Even outside of formal graduated systems, most jurisdictions set requirements for licensure that require or promote a learner period, during which road rules and other road safety knowledge must be gained and supervised-only driving is permitted in order to pass mandatory knowledge and practical driving tests. While education might be limited to driver handbooks, other official texts or individual web-based programs, a range of optional or mandatory government and private group-based initiatives have also evolved.

In some jurisdictions, learner driving can only be undertaken at specialist driving schools or under the direction of an accredited professional driving instructor (such as in China, Denmark, and Spain). In other jurisdictions, parents and other experienced drivers (sometimes with specific eligibility criteria and registration requirements) can also supervise a learner (such as in the United Kingdom and United States) or else learners choose between professional or lay options (such as in Austria and France). In the Australian context, both professional and lay supervision are permitted at learner drivers' discretion, and a mix of both is promoted.

One-on-one professional driving lessons taken on-road are considered to lay the groundwork or otherwise strengthen adherence to legal requirements (such as up-to-date road rule knowledge) and preparation for the practical driving test for independent licensure (such as, safe and preferred vehicle handling and maneuvering requirements); potentially also correcting any “bad habits” acquired from lay supervisors. Alternatively, lay supervision, commonly undertaken with parents, or other family and friends, is considered to broaden the experience learners gain. This is due to the greater variability in driving achieved, in contrast to the

typically one-hour professional lessons that commence at the learner's residence, therefore covering similar locations and often similar times of day and traffic conditions (see, e.g., [Groeger and Brady, 2004](#)).

While professional lessons clearly fall within the definition of training, lay supervision is typically characterized as "practice driving," which provides opportunity to develop a wide range of cognitive schema or mental representations of driving to facilitate rapid safer responses in critical situations. Falling somewhat between these are learner driver mentoring programs, in which volunteers provide supervision for otherwise disadvantaged youth who do not have access to lay supervisors, vehicles or funds for professional lessons in order to achieve the high level of learner driving (100–120 h) required by some Australian states (see, e.g., guidelines informed by previous research, [Soole et al., 2014](#)).

Group-based education initiatives for young drivers commonly are coordinated through schools and might also take place at school within regular school hours or at external venues at other times. Such programs address common young driver crash risks and might incorporate presentations from crash survivors, police, or emergency room surgeons, which aim to foster a deeper understanding of the risks inherent in driving or the potential consequences of risky driving to promote safer attitudes and behaviors. Peer-led or peer-to-peer education components also appears to be increasing, with some examples of improvements ([Buckley and Watson, 2014](#); [Cutello et al., 2020](#)).

Some programs also have been put in place to help prepare parents of young people for the tasks involved in supervising their child behind the wheel, although evaluations regarding the efficacy of these programs has been mixed ([Curry et al., 2015](#)). The more promising programs work to complement graduated driver licensing systems, such as a web-based program to increase the diversity of practice that is provided in parental supervised driving ([Mirman et al., 2014](#); [Toledo et al., 2012](#)), and a parent-teen agreement initiative (Checkpoints) that aims to increase parental limit setting on their children's driving when they first start to drive unsupervised ([Zakrajsek et al., 2013](#)).

Foundations of Current Wisdom in Novice Driver Education and Training

The United States pioneered an early Drivers' Ed model for learner drivers that is evident in these approaches and still integrated in some graduated licensing systems today. The approach required young drivers to undertake a combination of group-based classroom education focused on road safety knowledge and attitudes (minimum 30 h) plus in-vehicle training, either on-road, on a closed track or simulated (minimum 6 h). High-quality research evaluations of "state-of-the-art" applications in the United States and Australia in the 1970s and 1980s not only failed to identify a protective role, but there was some evidence participation resulted in earlier licensure, thereby increasing exposure to crashes and inflating risk (reviewed in [Senserrick, 2007](#)). Some programs even allowed time discounts on the learner tenure as an incentive, which continues to be demonstrated as counterproductive ([Begg and Brookland, 2015](#)). Further efforts to tailor such courses to the specific skill deficits of novices over the years, including in several European countries, have similarly been ineffective or counterproductive, particularly a practice broadly referred to as "skid training" to counter the identified over-representation of novices in a loss-of-control crashes (reviewed in [Senserrick and Mitsopoulos-Rubens, 2013](#)).

Such failures are variously attributed to the brevity or poor quality of the initiative or its evaluation, or a decay in skills from the time of learning to the time of need, especially school-based programs that target entire class levels and therefore often include many young people who do not yet have a permit or license to drive and might not do so for several months or even years later. A further critical factor in the counterproductive findings is the potential for such initiatives to increase novices' perceptions of their driving capabilities as much greater than actual—that is, a form of miscalibration rather than "overconfidence" as sometimes incorrectly labeled. This can lead the trained driver to take on driving situations that untrained drivers might avoid, such as driving in inclement weather or not sufficiently reducing their travel speed in such circumstances. Collectively, such work has led to an overarching conclusion that education and training are generally ineffective, basically because "it is not what you know, but what you do" that matters.

Theoretical and Emerging Research into Novice Driver Education and Training Best Practices

To some extent, this historical context continues to underlie much of the current "wisdom." However, there have been several more nuanced initiatives and exceptions to these global conclusions. In particular, a long literature focused specifically on "higher-order" hazard anticipation and perception skills has demonstrated not only that training can increase such skills, but that these skills transfer to real-world driving, can discriminate between novice, experienced and expert drivers, and increasingly also between crash- and non-crash-involved drivers ([Horswill et al., 2020](#); [Manley et al., 2020](#); [McDonald et al., 2015](#); [Thomas et al., 2016](#)). A recent study also suggests that hazard perception training can promote reduced engagement in secondary tasks ([Krishnan et al., 2019](#)), another prevalent crash risk factor, particularly among young drivers. Most jurisdictions in Australia now include hazard perception tests in their graduated licensing systems, which are currently being updated. This follows indications of the success of such tests in screening out drivers not ready to progress ([Boufous et al., 2011](#); [Horswill et al., 2015](#); [Wells et al., 2008](#)).

Attention to "high-order" skills, distinguished from basic vehicle-handling capacity, has increasingly expanded since emergence of a Finnish best-practice framework known as the Goals for Driver Education or GDE ([Hatakka et al., 2002](#)). The GDE presents as a hierarchical matrix with basic skills of "vehicle maneuvering" at the lowest level, successively increasing to maneuvering in traffic or

"mastery of traffic situations," to "goals and contexts for driving" that include decision making relative to specific driving situations (such as route planning, presence of peers and state of the driver), to "goals for life and skills for living" at the highest level, which moves beyond the specific driving context to broader cultural and social contexts (such as living in a location with a "car culture" or "cycling culture," and social and wider societal norms around drug use). Across the matrix for each of these levels are specific "knowledge and skills" and "risk-increasing factors," but also "self-evaluation and awareness skills." Best practice is considered to touch on all cells of the matrix, but not in a unidirectional manner, with lower levels considered to impact on higher levels and vice-versa. Reflecting on the historical context, traditional driver education has focused on the first "rows and columns" of the matrix, moved somewhat into the higher level of the goals and contexts for specific driving contexts, but rarely reached the wider societal context at the highest level, or included self-reflection components in relation to these or even lower levels.

More recent initiatives aligning with GDE self-evaluation and awareness skills include programs focused on "insight training," with the intent of giving novice drivers the ability to calibrate their perceptions of their driving skills with the reality of their driving skills and thereby foster safer attitudes towards driving risks (Horrey et al., 2015; Isler et al., 2011; Washington et al., 2011). Such programs teach drivers to self-assess and anticipate risk, focusing on higher-order skills as well as basic vehicle handling skills, such as demonstrating the physics of braking distance at different speeds and contrasting the long distances required to stop to the close following distances that drivers typically leave in traffic. At the highest broader societal level are "resilience-focused" programs, that aim more widely to empower youth to make informed decisions and adopt safer strategies not only to reduce their own exposure to risk, but also that of their friends and others, which may or may not include content specific to driving risks (Griffin et al., 2004; Senserrick et al., 2009). While there is reason for optimism regarding such approaches, more research is required to determine potential differential risks and benefits, particularly for young males (White et al., 2011).

Increasing attention to providing feedback to novices on their driving is a form of education that could be argued also to promote better self-reflection and self-assessment. This includes in-person feedback or feedback from the vehicle or on-line or via text messages from various programs and tests, as examples. Several studies have demonstrated that novice driving can be improved by providing feedback on their vehicle handling skills (e.g., Carney et al., 2010; Simons-Morton et al., 2013), speed management (e.g., Molloy et al., 2019), hazard perception (e.g., Horswill et al., 2017) and also headway in one small demonstration study (Arnold and VanHouten, 2020); but not impulse control in another body of work (Hatfield et al., 2018). There have been mixed results in also providing feedback to parents of young drivers about their child's driving, although one recent study suggests a key to the effectiveness of this approach is to provide parents with effective communication strategies (Peek-Asa et al., 2019).

Most recently, a GDE coding taxonomy has been developed to explore a range of higher-order spoken and non-verbal communications by professional instructors in learner driver lessons, using naturalistic driving methods (Watson-Brown et al., 2018). A pilot and larger main study in Australia found 15%–35% of such instruction was higher-order, with the main study finding a further 12% of chances for higher-order instruction were either not perceived or addressed with functional feedback only (Scott-Parker et al., 2014; Watson-Brown et al., under review). While seemingly low, somewhat comparable research in the United States on parental supervision of teen practice driving found between 6% to 15% could be identified as higher-order across three studies (Ehsani et al., 2015, 2017; Goodwin et al., 2014). Importantly, a survey of a corresponding cohort of young drivers in Australia found that the more professional higher-order instruction perceived the lower the engagement in both inattention and intentional risk-taking driving behaviors, which were mediated by a self-regulated safety orientation towards driving (Watson-Brown et al., 2019).

This is emerging research and needs further applications and evaluation, nonetheless, further exploration of the professional instruction in the Australian research found that the proportion of higher-order communication did not vary as might be expected according to the level of driving experience of the learner or instructor (Watson-Brown et al., under review). For example, there was no corresponding increase with increased learner driving hours, proportional use varied widely by instructor, but also on average was highest in lessons with learners who had less than 20 h of driving experience. This suggests, much like the established value in providing even experienced drivers with hazard perception training (e.g., Horswill et al., 2013), there might also be value in upskilling professional instructors, and possibly also parents, in how to extend their communications to learners drivers to be high-order, in order to deepen the learning and potentially better protect the driver once independently licensed.

Looking to the Future—Current and Emerging Driver Education and Training Needs

The nature of driving has been rapidly changing in recent years. Vehicles are being transformed as a consequence of the technological developments leading to automated driving. Although fully automated vehicles including driverless cars will not be commercially available in the short- or mid-term, the driving experience will be enhanced and supported by a wide range of technologies during the transition period. Advanced Driver Support Systems (ADAS), such as blind spot monitoring, lane departure warning, collision warning, and in-vehicle information systems, are being incorporated in increasing numbers in vehicles (Viereckl et al., 2016).

There is great expectation about the positive impact of these new systems on safe driving and road trauma (Cicchino, 2019; Spicer et al., 2018). However, ADAS bring new challenges for driver education and training. In particular, there are concerns about misperceptions or lack of awareness of ADAS functionalities among drivers, particularly those who learn to drive in vehicles with these technologies. This could result in negative behavioral adaptations among drivers such as taking advantage of or misusing the systems. For example, there are reports that when driving with adaptive cruise control drivers present delayed reactions times (Larsson et al., 2014; Shen and Neyens, 2017) and decreases in minimum time headway/time-to-collision (Bianchi-Piccinini

et al., 2015; Hoedemaeker and Brookhuis, 1998), as well as being more likely to engage in distractions (Dunn et al., 2019). In some extreme cases it has been reported that other road users reduce their protective behaviors in the presence of a vehicle known to have autonomous emergency braking (Kinosada et al., 2020). There is a need to understand the future education and training needs that ADAS and other technologies will bring for the transport system.

Education and training could have an important role in the safe up-take of in-vehicle technology. However, evidence suggests that they currently are insufficient and lack structure. A common finding from many studies around the world is that large groups of drivers do not even know if they possess a system. For example, in the Netherlands, it was found that the vast majority of drivers of vehicles with adaptive cruise control, lane departure warning, emergency brake and distance alert systems were largely unaware of owning ADAS (from 65% up to 83%; Harms et al., 2020). In another Dutch study, one-quarter of new car buyers had not received any information about ADAS fitted in the car (Boelhouwer et al., 2020). Another issue has been that even if drivers know that they possess a system, they do not understand the functioning or limitations of the ADAS. For example, a national cross-sectional study of drivers in Spain found that not knowing how to use the systems was one of the main reasons for not using ADAS, including fatigue detection systems and adaptive cruise control (Lijarcio et al., 2019). More concerning it seems that many drivers can be unaware of the limitations of the ADAS, such as the limitations of cameras, radars and other sensors that these technologies rely on, as demonstrated in United States research (McDonald et al., 2018). There is an important gap in upskilling drivers of all ages regarding the safe use of ADAS.

A major problem is that education and training about ADAS has been largely the responsibility of the driver. Generally, drivers are required to read the user manuals and complement this with other sources of information, such as via the internet. However, reports show that the majority of drivers use trial-and-error as opposed to user manuals or receiving instructions from the dealer (Harms et al., 2020). Drivers also report that user manuals can be difficult to understand, too long and contain insufficient information (Viktorová and Šucha, 2019). Inadequate training at the time of purchase is one of the most significant challenges for ADAS education and training. There is evidence that car sellers often do not have enough time to inform customers about ADAS, do not have the right training or education themselves, or show inconsistent quality (Abraham et al., 2018; Boelhouwer et al., 2020; McDonald et al., 2018). Other sources of education and training such as discussion with family or friends may provide insufficient information about ADAS risks (Oviedo-Trespalcacios et al., 2019).

This situation is extremely problematic because drivers may develop erroneous mental models of the ADAS that could result in misuse of the systems or encounter problems with ADAS during safety-critical situations. An example of this has been reported in the United States, with drivers of vehicles with lateral and longitudinal ADAS found to have greater odds of engaging in distracted driving behaviors (Dunn et al., 2019). Further, qualitative research has found that some drivers only realize the limitations of an ADAS while driving, such as only working within certain speed limits or issues operating in certain weather conditions (Viktorová and Šucha, 2019). Research from the United States reported that the current state of driver education on in-vehicle technologies is often misaligned with driver learning preference. Participants preferred receiving training at the point of sale or via a technology expert along with some other media, such as websites, vehicle manual, or in-vehicle computerized assistance (Abraham et al., 2018); yet as noted above, this does not appear to eventuate. Further developments are needed to guarantee effective educational and training activities on ADAS use.

Further, ADAS with visual interfaces, such as in-vehicle information systems (IVIS), are known to present distraction risks for many drivers (Oviedo-Trespalcacios et al., 2019). Given that IVIS are key elements of the human-machine interface, it is likely that their prevalence will increase (Statista, 2017). Traditional approaches to education of drivers have targeted prevention of distractions, whereas most recent vehicles require drivers to share and interact with an increased number of systems, such as IVIS and head-up displays. Therefore, divergent with traditional education and training approaches that focus on avoiding distractions, there is a need to upskill drivers to engage safely in distractions with these ADAS. An example of this is the U.S. FOrward Concentration and Attention Learning (FOCAL) educational program (Unverricht et al., 2019). FOCAL educational training develops drivers' capacity to self-regulate off road glances. Experiments after training confirm that the extent of distraction can be reduced. Drivers who received FOCAL training engaged in fewer in-vehicle glances longer than two seconds (generally accepted as the minimum safety threshold) compared to drivers who received traditional education on distraction-related risks and road rules. Future education and training initiatives will need to consider the need to upskill drivers in the correct interactions with ADAS that include safer and less safe distraction.

Another important concern in the field is that extensive experience with ADAS might result in skill atrophy when equivalent systems are not available, potentially increasing risk of missing detection of a pedestrian for example (Miller and Boyle, 2019). This particularly applies to young novice drivers, given common changing of vehicle use as a learner between a professional instructor's vehicle, their parents' vehicles and potential transition to their first own vehicle, which is more likely to be older and have fewer safety features (Eichelberger et al., 2015; Keall and Newstead, 2010). But also this applies to experienced drivers who engage in the rental/for-hire vehicle market, such as business travelers and tourists, who might switch to and from various vehicles as they travel to different locations. Such use might be short-term and likewise also demand for brief education and training initiatives. As yet however, evidence-based examples are lacking. There are still open questions about the role of education and training programs designed to allow drivers to maintain relevant skills transferring between vehicles with more or fewer ADAS and, continuing to the future, also higher and lower levels of automation.

On-road trials of automated vehicles (AVs) are currently underway in many countries. The Society of Automotive Engineers (SAE International, 2018) defines six levels of automation, ranging from no automation (Level 0) to full automation (Level 5). It has been predicted that AVs will reduce human error associated with crashes. However, more recent research has argued that AVs may increase

passive fatigue, that is, fatigue which is associated with low workload, such as monitoring vehicle systems rather than operating the vehicle (Matthews et al., 2019). Increases in such fatigue has potential to increase crash risk when a driver is requested to take back control of the vehicle. These new advances in vehicle technologies will change the role of a driver to one of observing the vehicle functions and intervening when requested (or when required), rather than actively operating the vehicle at all times. Therefore, driver education and training are likely to be vital in increasing users' understanding of this new human-automation interaction as well as adaptive changes needed when transitioning from higher to lower level vehicles and vice-versa.

The need for increased education and training can be demonstrated in media reports of crashes that have occurred in the United States involving self-driving vehicles. In 2018, a vehicle travelling in automated mode in Arizona hit a pedestrian, who later died in hospital. At the time of the crash the human operator of the vehicle was watching their phone and not monitoring the road environment. Similarly, a Tesla vehicle operating in self-driving mode in Florida in 2016 failed to distinguish a truck, resulting in a fatal collision. In both cases, the driver (or operator) should have been monitoring the road environment and have interacted by taking back control of the vehicle but failed to do so. These cases further highlight the need to educate drivers on vehicle capabilities, including such limitations associated with AV technologies.

To this end, some recent research in the AV literature has examined the effectiveness of different types of training programs, including, Virtual Reality systems, Head-Mounted display (i.e., a device which is worn on the head), visual (e.g., video) and written education resources, and experiencing automated functions in a driving simulator (e.g., Forster et al., 2020; Payre et al. 2017; Sportillo et al., 2018). While such research is in its infancy of assessing which type(s) of training programs are most effective, what has been found is that individuals who complete some type of training are more equipped to take back control of the vehicle compared to those who complete no (or limited) training. For example, in France, it was found training improved response times in a driving simulator study (Payre et al., 2017). Further, participants who received elaborated training (i.e., read text explaining automated driving, answered questions with the experimenter, and watched a short video on how to engage and take back control of the vehicle) reported greater trust in automated driving after the intervention, compared to participants who did not receive this prior training before the simulator drive. Once AVs are more commonly available and appropriate legislation has been introduced, there will be more opportunities for people to increase their skills and gain experience in using these AV functions on closed tracks and on open roads.

Concluding Comments

The ways in which we travel are rapidly evolving. Some research suggests that young people are delaying driver licensure for a variety of reasons (Thigpen and Handy, 2018). Travel modes have expanded to include more shared vehicles, as well as an array of electronic bicycles and "rideables" (such as e-scooters, e-unicycles), and demand for more livable cities is increasing. So too should be the demand for more innovative, forward-thinking driver education and training. Relying on traditional approaches to "tick the box" and historic "wisdom" that such approaches cannot be effective provides an excuse that prevents greater efforts to improve such practices. We argue that such complacency is not justifiable, particularly with the potential for counterproductive outcomes by relying on the status quo. There are important types of knowledge and skills that need to be taught, and examples that this can be done without miscalibration risk, and with true potential to play a protective role for novice drivers; one of the most at-risk driver groups. Therefore, it is imperative among both the academic community and industry that efforts continue, not to dismiss education and training, but to persevere to make optimal, agile improvements and demonstrate effectiveness through high-quality evaluation.

Brief Background to Advertising as a Road Safety Intervention

As a road safety intervention, advertising campaigns represent a long-standing approach. In years gone by, more traditional broadcast media such as television, radio, and print have been the key dissemination channels of such campaigns. Of these broadcast media, perhaps not surprisingly given its potential reach, early meta-analytical evidence of road safety advertising campaigns supported the effectiveness of television relative to other message media (Elliott, 1993). Presently, the use of these traditional media types remains popular among road safety agencies; however, the communication landscape has changed quite dramatically over recent years due to the proliferation and increased use of technology that has led to the identification of new, digital and online communication approaches. Coupled with this changing communication landscape, is the need to be aware of different approaches to campaigns and campaign content and how best to ensure that the messaging reaches an intended audience and has the desired effect of changing attitudes and, ultimately, behavior.

As earlier articles of this book have alluded to, road trauma is a leading contributor to the global burden of disease and injury (Vos et al., 2020). With economies adversely impacted in post-COVID times, road safety authorities the world over will be especially focused on evidence-based interventions that can be delivered at relatively low cost. Thus, now more so than ever, it is critical to understand the role and effectiveness of road safety advertising as a countermeasure and to be aware of gaps in knowledge that future research and practice must address.

With this in mind, this article focuses on road safety advertising campaigns—what influences their effectiveness, what factors underpin successful campaigns, and what are the on-going research priorities. The article aims to identify what is known and what is yet to be known, thereby setting a research agenda for the future.

What is the Role of Road Safety Advertising?

Human factors have long been recognized as contributing to road crashes (Treat et al., 1979). Among the major contributors to such trauma are the “Fatal 5” (Queensland Police Service, 2020), which include speeding, drink driving, distraction, not wearing a seatbelt, and fatigue. The extent to which human decision-making underpins whether or not one engages in each of these behaviors, highlights the important role that advertising campaigns can play in raising awareness of the risks and strategies to prevent engaging in such risky behavior as well as, ultimately, changing attitudes and behaviors so that individuals opt to instead engage in safer, legal on-road behaviors. As Lewis et al. (2019a,b) outline in their review of the role of advertising from a Traffic Safety Culture perspective, road safety advertising can play a reinforcing or transforming role. Specifically, advertising may reinforce the purpose of traffic-laws and their associated enforcement and/or it may seek to “transform” community values and attitudes (see also Watson and Soole, 2013). For instance, with regard to the reinforcing role and in the case of drink driving, road safety advertising may seek to highlight the threat of police detection (e.g., random breath testing) associated with drink driving. In contrast, a transforming approach would focus on changing values and attitudes by highlighting the physical (e.g., death) and emotional (e.g., loss of loved one) harm inflicted upon the victims, their families, and the wider community from alcohol-related road crashes. The reinforcing and transforming approaches are not mutually exclusive and can co-occur within the same advertising campaign (Lewis et al., 2019a,b; Watson and Soole, 2013).

What are the Factors that Underpin Effective Road Safety Advertising?

The available evidence attests to an extensive and varied array of factors that influence the potential effectiveness of road safety advertising. Indeed, it is beyond the scope of this current article to be able to provide an exhaustive review of all such factors. In taking a step back though, before talking about factors that influence “effectiveness”, it also needs to be acknowledged that the

Figure 1 The step approach to message design and testing (SatMDT; Lewis et al., 2016a).

conceptualization of “effectiveness” itself is ambiguous in this context. Due to this conceptual ambiguity, any comparisons across studies can be akin to the adage of “comparing apples and oranges”. For instance, depending on campaign objectives, effectiveness may be assessed in terms of awareness raising, attitude change, or actual behavior change (Elliott, 1993). Appreciably, achieving evidence of having raised awareness of a campaign and/or issue may be more readily achievable (and measurable) than determining the extent to which a particular campaign may have achieved changes in a particular behavior, such as having drivers increase their compliance with the speed limit following their exposure to an anti-speeding campaign.

The challenges associated with defining message outcomes also extends to criticisms directed at evidence being based predominantly on effectiveness as defined in terms of the extent of acceptance achieved as opposed to the extent of message rejection. Theoretical and empirical evidence attests to the need to consider outcomes also in terms of the extent of rejection (e.g., Witte, 1992; see also Lewis et al., 2016a); however, relative to the focus on acceptance, fewer studies incorporate measures of rejection. This omission is problematic to the extent that evidence attests to such outcomes as not being mutually exclusive (Lewis et al., 2010; Tay and Watson, 2002; Witte, 1992) and, thus, to understand the *overall* or *net* effectiveness of a campaign or message, it is necessary to assess rates of both acceptance and rejection.

In the attempt to consolidate the extant evidence in the field in a way that could be used to develop message content and aid message evaluation, the Step approach to Message Design and Testing (SatMDT; Lewis et al., 2016a) was developed (see Fig. 1). The SatMDT is based on social psychological theories of decision making and persuasion including the Theory of Planned Behaviour (TPB; Ajzen, 1991), Social Learning Theory (Bandura, 1969), the Extended Parallel Process Model (EPPM; Witte, 1992), and the Elaboration Likelihood Model (ELM; Petty and Cacioppo, 1986). Given the framework has been outlined comprehensively elsewhere (see Lewis et al., 2016a, 2019a,b), a similar outline will not be presented herein. Instead, noting briefly that, as Fig. 1 of the SatMDT shows, the framework outlines the message design and evaluation process in a series of steps. At each step, the framework identifies a range of key considerations. For instance, the importance of considering message acceptance and rejection in any attempts to evaluate message effectiveness, as was discussed previously, is captured as key consideration within the Message Evaluation step, Step 4, of the framework. When developing message content, as addressed within Step 2 of the framework, factors including emotional appeal type and modeling of behavior are highlighted as evidence-based factors to consider. As will be discussed further shortly, the choice of an emotional appeal type represents a long-standing message factor associated with much contention with Janis and Feshback credited as having conducted the first study of fear and persuasion back in the early 1950s (see Janis and Feshback, 1953).

Of note, the utility of the framework in aiding in the design of road safety messages has been demonstrated across a number of studies and in relation to various road user behaviors and issues including, for example, speeding (in general community [Lewis et al., 2017]), in organizational fleets [Lewis and Newnam, 2011]), speeding in school zones (Glendon and Lewis, 2019), distraction (Gauld et al., 2014; Gauld et al., 2020), child pedestrian safety (Murray et al., 2016), child restraint use (Lewis et al., 2016b), tailgating/vehicle headway (Schramm et al., 2012), drink walking ([intoxicated pedestrians]; via comments provided by the first author for a campaign developed by the Queensland Department of Transport and Main Roads, <https://streetsmarts.initiatives.qld.gov.au/pedestrians/drink-walking>), as well as messaging encouraging use of cooperative and automated vehicles in the future when

they become publicly available (Lewis et al., 2020a). Moreover, its applicability has been demonstrated in relation to the development and/or evaluation of messaging via various media including, for example, television (Lewis et al., 2016b), highway Variable Message Signs ([VMS]; Schramm et al., 2012), portable road-side VMS (Glendon and Lewis, 2019), online/digital (Lewis et al., 2020b), radio (Lewis et al., 2017), and print advertisements (Lewis et al., 2020b). Without question, equally important to specifying from the outset what the intended objectives of a particular campaign are (i.e., raise awareness or change behavior) is to determine the intended media that will be used to disseminate the messaging.

As was noted earlier, and perhaps representing one of the longest standing controversies in the field of health persuasion has been the role of emotion and, in particular, whether or not to rely upon fear to achieve persuasion. Suffice to say, whether or not a proponent or opponent of using fear, evidence suggests the use of fear is to be done so cautiously and the relationship between fear and persuasion is complex. It is acknowledged that, as individuals we all fear different threats to different extents and, as such, it is more about ensuring the threatening stimulus is the most salient and likely to appeal to an intended target audience. This acknowledgment highlights it is important to appreciate that, even when designed to be a “fear appeal”, such an appeal may not actually elicit fear if the threat depicted is not considered a threat that one feels personally susceptible to or as severe. In other words, it is the cognitive processing and appraising of a threat and whether it is relevant and severe that determines whether or not one is likely to experience fear (and as is addressed within Witte’s 1992 Extended Parallel Process Model [EPPM]).

Furthermore, according to models such as the EPPM, it is also not just about the threat but also about the extent to which a message may incorporate strategies that an individual believes are useful in preventing or reducing the threat and they are strategies that they can see themselves implementing; defined in the literature as response efficacy and message self-efficacy, respectively (Witte, 1992). Indeed, meta-analytical evidence attests to the fact that perceived susceptibility and severity, as well as perceptions of efficacy (in terms of response and message self-efficacy) are all positive predictors of message acceptance (see Floyd et al., 2000); however, it is efficacy that is the most important predictor and, thus, crucial determinant likely to increase acceptance and minimize rejection (Lewis et al., 2010).

Despite evidence supporting the important role that efficacy plays in message effectiveness, recent research has suggested that response efficacy is not always incorporated within road safety advertising campaigns. For example, Diegelmann et al. (2020), in a study of mobile phone use while driving campaigns in the UK, reported that response efficacy was rarely incorporated within online campaigns. Similarly, Cismaru (2014) found that fewer than half of the “texting while driving” campaigns included in their analysis of campaigns in the UK, Canada, and USA, had incorporated response efficacy. Another study found only one out of seven road safety messages in Russia had incorporated response efficacy (Ngondo and Klyueva, 2019). Such findings signal the need for greater alignment between research and practice to the extent that response efficacy, a key factor recognized as enhancing acceptance and minimizing rejection, is not always incorporated within road safety advertising messages.

Although traditionally, strong shock-based approaches threatening potential death or injury in a road crash as a result of engaging in risky and/or illegal behavior represented a commonly implemented approach in Australian road safety advertising (Lewis et al., 2019a,b), recent campaigns have tended to not rely as heavily upon such strong physical threats or at least not to rely exclusively upon them as the only approach to presenting road safety messaging. This change is supported by evidence with a meta-analysis conducted by Carey et al. (2013) finding that exposure to such appeals was not a significant determinant of driving outcomes. Additionally, Lewis et al. (2008) found the persuasiveness of fear-evoking emotional appeals for anti-drink driving messages to be greater immediately after exposure but reduce over time, while Anakwah et al. (2015) found that fear-arousing messages did not alter the attitudes of risky drivers.

Research has also found that the likely effectiveness of threat appeals differs between males and females, with males less influenced by messages that incorporated threats of physical harm than females (Lewis et al., 2007a). Similarly, Tay and Ozanne (2002) found that females were more influenced by threat appeals, with a reduction in fatal crashes occurring among females, but not young males, following exposure to a threat-based campaign (Tay and Ozanne, 2002). A recent study by Gauld et al. (2020) examined the effectiveness of three negative emotion-based messages addressing driver distraction and, in particular, smartphone use while driving among young drivers. They found that females were significantly more likely to report the messages as being effective, while the males were significantly more likely to report rejection (i.e., avoidance or denial). In a study conducted by Rodrigues et al. (2015), the researchers explored gender differences with regards to drivers’ perceptions of the effectiveness of road safety advertising campaigns in Portugal. They found that females reported significantly higher intentions to enact the advice offered by the campaigns than males, further highlighting the impact of gender on road safety message effectiveness. To the extent that evidence also highlights that males and females differ in regards to their engagement in risky driving behaviors, such as speeding and mobile phone use while driving (Oviedo-Trespalacios and Scott-Parker, 2018; Oviedo-Trespalacios et al., 2019; Rhodes and Pivik, 2011), collectively, such evidence serves as an important reminder that, consistent with the first step of the SatMDT framework, knowing the intended target audience and what underpins their engagement in particular behaviors is the key first step in message development.

As an evidence-based approach to understanding more about the factors that underpin individuals’ engagement in particular behaviors, the Theory of Planned Behaviour ([TPB]; Ajzen, 1991) offers much insight into the cognitions underpinning individuals’ decisions. Evidence based on the model supports the fact that understanding more about individuals’ pre-existing beliefs about an issue or behavior aids in the prediction of their intentions to engage in risky or unsafe driving behaviors (Atombo et al., 2016; Rowe et al., 2016). Hence, it follows that the identification of these underlying beliefs influencing individuals’ decision-making would provide key foci for the development of targeted road safety advertising (Lewis et al., 2016a). Some studies have identified critical beliefs as potential targets for public education messages targeting young drivers’ engagement in speeding (Horvath et al., 2012) and

smartphone use while driving (Gauld et al., 2016). For instance, the desire to feel in control was a salient advantage of speeding, while infringements were a disadvantage (Lewis et al., 2013). Thus, a message to reduce speeding could focus on the monetary aspect of engaging in this behavior (i.e., waste of a day's pay), while another message could emphasize that drivers are more in control when they are not speeding, considering how they are now more attentive of their driving (Lewis et al., 2013). Given the importance of such underpinning beliefs, it is perhaps not surprising that the identification of beliefs in accordance with the TPB is a key aspect within Step 1 of the SatMDT framework.

Once this formative phase has been conducted and the insights used to inform message content, it is also as important to ensure that concept testing of the messaging occurs with members of the intended target audience. Such testing ensures that messages are functioning as intended with those in the target group. The importance of undertaking such testing is reflected in its being designated as a key step, specifically the third step, within the SatMDT framework.

While the effectiveness of fear-based approaches can vary across demographic groups, an important consideration is the likely effectiveness of alternative emotional appeals. A growing body of evidence supports the role that positive approaches such as humor and pride may play in the road safety advertising context (Lewis et al., 2008). That said, while supporting the role that positive emotions can play in the context of road safety advertising as an alternative to fear, the evidence also highlights that the effectiveness of humorous messaging may also vary across different demographics. For instance, Lewis et al. (2008) found, in a study on negative and positive anti-speeding messages, that while males tended to be more influenced by the positive messaging than the negative, fear-based messaging, for females, opposite findings emerged. Similarly, Plant et al., (2017) found that anti-speeding messages which evoked positive emotions were found to reduce young drivers' speeding behavior.

Similar to the use of fear, evidence has cautioned that the use of humor in road safety campaigns must be appropriate; for instance, humor should never be associated with serious, negative outcomes such as road crashes (Lewis et al., 2007b). One of the potential advantages of using positive emotion-based approaches is that they may more readily (relative to negative, fear-based approaches) enable the use of the modeling of positive or safe behaviors and the rewards or, at least the avoidance of negative outcomes, being shown as consequences of engaging in such positive, safe behaviors. In other words, by their nature, the use of positive behavioral modeling aligns well with the use of positive approaches which may seek to elicit more positive feelings in audience members as to having done the right thing and being able to feel positively about that. In contrast, a typical negative or fear-based approach couples depiction of an individual engaging in an unsafe, risky, and/or illegal behavior (e.g., drink driving) and accompanies it with the negative consequences that may result (e.g., being caught and fined by police, being injured in a road crash).

Research Priorities Going Forward

In this final section, we overview what we consider are some of the most pressing areas of need with respect to furthering understanding the role and effectiveness of advertising as a road safety intervention. We preface this section by acknowledging that our intent is not to offer an exhaustive list but rather to provide some suggestions regarding potential avenues to advance contemporary knowledge.

First, there is need to understand more about road safety advertising in the online context. Not surprisingly given that there are decades of campaigns that have been disseminated via traditional broadcast media, much of the available evidence has been on the use and effectiveness of messaging delivered via these more traditional platforms. However, traditional media is a *one-way communication* platform, whereas digital communication is *dynamic*, unpredictable, and one in which an individual can be a co-creator of content. As people curate their "self" online, factors relating to identity, impression management, and normative expectations are likely to influence their responses and likelihood to contribute to digital campaigns (e.g., whether to post, share, or like content). Although online analytics reveal the numbers of "likes" and shares that a campaign receives, the key question is whether an individual ultimately adopts its recommendations and, therefore, changes their attitudes and behaviors. Traditional models of persuasion offer no guidance on the anticipated correspondence between these analytics and behavior change. Thus, traditional frameworks can neither account for the intricacies and the complex interplay of factors that influence an individual's engagement with and the effectiveness of digital campaigns, nor can these frameworks determine the ability of such communications to change people's attitudes and behavior.

This need is only too apparent when considering that, in Australia, advertising spend on digital advertising is projected to reach over \$9 million in 2020 (Statista, 2020). With it fast approaching 30 years since a seminal meta-analysis on road safety advertising campaigns was published (Elliott, 1993), the field would benefit from a meta-analytic review that captured the effect sizes associated with various media including communication platforms available via the digital context. In 1993, Elliott concluded that it was television that was associated with the largest effect size relative to the other traditional media. This finding was not considered that surprising given television was the medium associated with the greatest potential reach. Nowadays, however, that is not necessarily the case with particular demographics, such as young adults, likely to rely more upon online and digital options for their communication and information-seeking needs (Murray and Lewis, 2011; Wundersitz et al., 2010).

Extending upon this, there is a need to understand more about the types of messaging approaches likely to be effective for online platforms. For instance, with regards to advertising campaigns in general (and not road safety advertising in particular), some research has explored the emotional appeal type of viral campaigns. Hsieh et al. (2012), for instance, found comedic or humorous online videos to play an important role in influencing positive attitudes towards a received video, as well as intentions to forward the video onto others. Specifically, these types of videos can elicit positive emotions in viewers and encourage them to share their

emotions with others (Hsieh et al., 2012). These findings are in line with another study conducted by Berger and Milkman (2012), who found that positive online content was more likely to be highly shared, even after controlling for the frequency of occurrence, and online content that evoked a de-activating emotion (e.g., sadness) was less likely to go viral.

Second, there remains a gap in knowledge when considering the role and effectiveness of different types of humor in road safety advertising (Lewis et al., 2018) and in relation to the persuasive effects of other types of emotion more broadly. There is also need to understand the relative effectiveness of different types of humor and other emotions more broadly in relation to different audiences.

Third, there is a need to continue efforts regarding the application of the most robust methodological approaches to assess the effects of road safety advertising. Much of the available evidence is based on self-report methods such as questionnaires (Borawska et al., 2020). Although such information provides insights into individuals' perceptions, it would also be useful to develop a deeper understanding of individuals' automatic and unconscious reactions towards different emotional appeals (Borawska et al., 2020). This understanding could be gained through various neuroscientific methods such as psychophysiological (e.g., heart rate, skin conductance; Ordoñana et al., 2009) and electrophysiological (e.g., EEG; Borawska et al., 2020) measures. Moreover, research has found objective measures (e.g., skin conductance response, GPS devices) could be used in conjunction with self-report measures to understand both the persuasive processing and outcomes of emotion-based anti-speeding advertisements as well as confirm the robustness of the respective methods (Kaye et al., 2016). Another important consideration when evaluating a campaign is to ensure comparisons are made between groups of individuals who have seen/heard a campaign message as well as those who have not. Those who do not see/hear the message can be considered as a baseline or control group. The responses from those who did see/hear the message can be compared with the control group and, thus, a more comprehensive understanding of the nature and extent of changes can be determined (Kaye et al., 2016; Robertson and Pashley, 2015).

Finally, and extending upon the preceding point, there is an ongoing need for road safety advertising campaigns to be evaluated and for these evaluations to be robust and theoretically underpinned (Lewis et al., 2016). Such evaluations ensure that the evidence-base continues to grow and that lessons are learned as to how and why a particular campaign was or was not successful. For example, there remains a need to explore the relative effectiveness of road safety advertising when it is used to support other initiatives versus being used in isolation.

Concluding Comments

This article provided a review of where knowledge currently stands regarding the role and effectiveness of advertising as a road safety intervention and concluded by highlighting some suggested directions for future research. While the nature of road safety advertising has evolved over the last two decades, it continues to be relied on extensively to bring about changes in road safety awareness, attitudes and behaviors and to support other initiatives. Hence, it is essential that research continues to identify whether the resources devoted to road safety advertising are being used in the most optimal way.

Introduction

Traffic collisions are a leading cause of deaths and serious injuries in many countries and cost societies an average of one-two percent of their gross national product (WHO, 2003). In an effort to reduce and prevention collisions, many countries have implemented a variety of engineering, education and enforcement strategies. The role of traffic law enforcement is to ensure that road users comply with the traffic laws by apprehending and punishing those who commit a violation. If traffic legislations are designed to improve safety, then reducing violations will result in fewer traffic collisions.

Traffic rules and regulations are designed to prevent risky road user behaviors and ensure a safe road environment. However, not all road users will obey all them and many road users may also unintentionally violate them. Regardless of intention, a traffic law violation may significantly increase the likelihood of a traffic collision, resulting in property-damage, injuries and deaths. Therefore, it is important that traffic laws be enforced adequately to reduce and prevent illegal and risky road user behaviors.

Although there are a multitude of laws covering a variety of areas, including vehicle standards and safe operations, most of the foci in the traffic safety literature have been on high risk driver behaviors such as speeding, drink-driving, not wearing seatbelt, driving while fatigued, and distracted driving. The need for and the effectiveness of the enforcement of these laws have been well research and documented in the literature.

The purpose of this book chapter is to provide a conceptual framework to inform the development and evaluation of traffic law enforcement, as well as to provide some possible explanation for some of the mixed results obtained in previous studies.

Deterrence Theory

The European "Escape" Project proposed a Compliance Model of traffic law enforcement that described the process: Legislation → enforcement → Objective Risk → Subjective Risk → Deterrence → Compliance (Mäkinen et al., 2003). Although the model also has a secondary path in which other support measures can affect the objective and subjective risks, deterrence is the main mechanism driving compliance in this model.

Criminology Perspective

In criminology and social psychology, the concept of deterrence is used to describe the prevention of criminal behavior through legal sanctions or punishment. Deterrence refers to compliance produced by the existence and administration of criminal law rather than

some other source (Meier and Johnson, 1977). Deterrence occurs when a particular sanction functions to prevent the occurrence of an act or is thought to decrease the probability of the act's occurrence. Traditionally, deterrence has been conceptualized as involving two distinct types of processes: specific deterrence and general deterrence. Specific deterrence operates when an individual who has committed a crime and has been sanctioned refrains from committing additional criminal acts for fear of another punishment. General deterrence occurs when a would-be offender refrains from committing a crime because another has been punished for offending.

Social Learning Perspective

In social learning theory, general deterrence is defined as the deterrent effect of indirect experience with punishment and punishment avoidance while specific deterrence is defined as the deterrent effect of direct experience with punishment and punishment avoidance (Stafford and Warr, 1993). This approach has several advantages over the traditional definition. First, it recognized the possibility that both general deterrence and specific deterrence could operate for any given person or in any population. Second, it treated punishment avoidance as analytically distinct from the experience of suffering a punishment. Third, it was compatible with contemporary learning theory, particularly the distinction between observational/vicarious learning and experiential learning.

Economic Perspective

Consistent with these views, the main focus of the deterrence theory in the field of economics is on increasing the individual's perceived expected cost of engaging in an illegal activity (Tay, 2005a, 2005b, 2005c, 2005d). An increase in the expected cost is posited to decrease the level of illegal activity consumed by the individual or decrease the likelihood of the individual to engage in the illegal activity. This increase in the perceived cost could be a result of an increase in any or all of the severity of the sanction, the probability of apprehension or the swiftness of punishment.

Deterrence Mechanism

There are three factors that influence the effectiveness of any deterrence policy based on the concept of punishment: certainty of punishment, severity of punishment, and immediacy of punishment. In the road safety arena, the severity of the punishment is determined mainly by the legislature whereas the swiftness of the punishment is determined mainly by the administrative or judiciary system. The main impetus of law enforcement therefore is in increasing the certainty of apprehension and punishment.

Certainty of Punishment

From an economic perspective, an increase in the perceived probability of apprehension will increase the expected cost of committing in violation and thus reduce the likelihood of the violation. The perceived probability of apprehension is a subjective probability that depends on the individual's information set. Two of the major determinants of this information set are the level of police presence on the roads and the hit (apprehension) rate. It can be argued that the former focuses more on general deterrence whereas the latter focuses more on specific deterrence. Thus, traffic law enforcement agencies need to consider optimal mix of covert versus overt operations, high traffic versus high violation areas, and manned versus automated enforcement (Tay, 2009, 2010).

Severity of Punishment

From an economic perspective, an increase in the severity of punishment will increase the expected cost of committing in violation and thus reduce the likelihood of the violation. Although the severity of punishment is determined mainly by the legislature, law enforcement officers often have some discretion, such as issuing a warning or a ticket. Ennis (1967) studied the effect of warning versus citation whereby each technique was tried on 100 speeding motorists and found that 33% of those issued a citation exceeded the speed again while 65% of those issued a warning exceeded the speed again 5 miles down the road. Thus, there is evidence that the severity of punishment has an effect through specific deterrence. However, Mann et al. (1991) found that increasing the severity of punishment, such as amount of fine, length of probation and length of jail, did not have any significant effect of collision reduction. Overall, the evidence suggests that the type of punishment is a better measure of severity than the absolute amount (within certain limits) of the same sanction.

Immediacy of Punishment

From an economic perspective, a delay in punishment, especially financial penalty, will decrease the expected cost of committing in violation and thus increase the likelihood of the violation. However, since the delay is small, this effect is unlikely to be significant. From a learning perspective, immediate feedback will provide a better association between violation and punishment. Moreover, a longer delay in punishment will also provide more opportunities to learn from punishment avoidance, especially when the certainty of punishment is low. Experimental studies on the effect of punishment on behavior generally indicate that immediate punishment

is far more effective than delayed punishment. Hence, all else held constant, manned enforcement which provides an immediate sanction should be more effective than automated enforcement which has a longer delay between the time of violation and the time when the driver received an infringement notice (Tay, 2009).

Punishment and Punishment Avoidance

One of the key assumptions underlying both the learning and economic perspectives of deterrence theory is that drivers learn from both punishment and punishment avoidance. Based on their own experience of punishment or punishment avoidance and the experience of others, drivers will revise their perceptions of the probability of being caught. This learning process is especially true for commuters and drivers who pass through a location regularly. In particular, many drivers will learn relatively quickly for fixed location enforcement, such as road safety cameras. This adaptive learning from punishment and maladaptive learning from punishment avoidance is critical consideration when designing the optimal enforcement strategy, in terms of spatial and temporal coverage, given a limited amount of resources (Tay and de Barros, 2009, 2011).

General and Specific Deterrence

Both general and specific deterrence are likely to be present in most types of enforcement activities. In the case of road safety cameras, there is no need for the actual presence of police. Instead, general deterrence is assured by the presence of camera installations and equipment, such as enforcement signage, the camera casings and poles. It should be stressed that the presence of camera casings can only provide a general deterrent effect and not specific deterrent effect. Tay (2005a, 2009) and Tay and de Barros (2011) argued that without some threshold level of punishment and specific deterrence, efforts aimed at general deterrence do not work because drivers will soon realize that few offenders ever get caught and punished. Therefore, the common belief that the presence of camera casings at camera-enforced locations is sufficient to deter drivers is only consistent with the mechanism of general deterrence but not specific deterrence and its overall effectiveness is unknown. Thus, traffic law enforcement agencies need to consider optimal mix of covert versus overt operations, high traffic versus high violation areas, and manned versus automated enforcement, to produce the maximum overall deterrence effect (Tay, 2009, 2010; Tay and de Barros, 2006, 2011).

Enforcement Models

Steady States of Violation Rates

We can assume that a significant proportion of the drivers are risk adverse or have a morale attachment to the law. These people will generally not violate the road rules and will form a limit or the upper threshold of the violation rate. However, there will be a small proportion of the drivers who are low to moderate risk risk-takers. They will speed, run a red light, not wear a seatbelt or drink-and-drive under some circumstances, such as driving under time pressure or under pressure from impatient drivers behind them, driving for a short distance, and when they think that they are able to get away with the offence without being caught. A significant portion of this group of errant drivers can be deterred from committing an offence if their perceived probability of apprehension is sufficiently high. Finally, there exist a very small proportion of high-risk drivers who will speed, run the red, not wear and seatbelt or drink and drive regardless of the perceived probability of apprehension. They include drivers who are very high-risk takers, drivers with very high value of time or high income relative to the monetary penalty. These drivers will form the lower threshold of the violation rate, until they are effectively remove from the driving, including driving unlicensed.

The above theoretical conceptualization leads to three simple hypotheses about violation rates. First, even if enforcement is absent permanently or for an extended period of time, the violation rate will not be 100% at most locations. There is an upper steady state limit. Second, even if the enforcement is present permanently or for an extended period of time, the violation rate will not be zero. There is a lower steady state limit. Third, when enforcement is intermittent, the violation rate at any location and time will be between these two thresholds and will depend on the durations of enforcement and the apprehension rate. The steady state thresholds or limits will depend on the type of behavior, risk profile of the driving population as well as the severity and swiftness of punishment.

Time and Distance Halo

Besides having a differential effect on different road user types, enforcement also has a differential effect by time and space. This is particularly true for transient behaviors such as speeding and red light running. Time halo can be defined as the length of time that the effects of enforcement on drivers' behavior continue after the enforcement operations have been ended. Distance halo is defined as the distance over which the effects of an enforcement operation is effective.

Although time and distance halos are commonly assumed to be a step function in practice, they should theoretically be considered as a decreasing function from the time when enforcement ceases or from the location of the enforcement. The rate of decrease will depend largely on the type of enforcement and the road users' risk profile. Red light camera, for example, may have a slower rate of decrease over time than mobile speed enforcement but has a faster rate of decrease over distance. Even for the same type of enforcement, such as mobile speed camera, some drivers will resume speeding much earlier (either by time or distance) than

Figure 1 Adaptive learning and maladaptive learning.

others after they have passed the police vehicles. Assuming that the driving population is normally distributed, then the deterrence effect is expected to decrease exponentially with time and space.

Halo Effect, Learning and Violation Rate

As shown in **Fig. 1**, starting from an absence position, when enforcement is first present on at any location, the violation rates is expected to show an exponentially decreasing effect until it reaches a lower steady state threshold. We shall call this phase the adaptive learning phase where drivers learn over time that enforcement is present and decrease their likelihood of committing a violation. If the enforcement continues for a sufficient period of time, the violation rate will reach and remain at the lower steady state level. Conversely, when enforcement is absent or removed, drivers will learn eventually that there is no enforcement and increase their likelihood of committing a violation. This time period is associated with maladaptive learning and is typically known as the time and/or distance halo in traffic enforcement. [Tay and De Barros \(2009, 2011\)](#) found that the maladaptive learning period is much shorter than the adaptive learning period.

Halo Effect and Enforcement Coverage

It is a common practice for enforcement to be rotation around different locations due to time and budget constraints. Hence, it is important to understand the relationship between halo effects and violation rate over time and space to optimize the allocation of enforcement resources.

Once the time halo is ascertained, the maximum time between successive enforcement or the maximum length of nonenforced time to achieve effective coverage is known. The ratio of the required enforced time to nonenforced time will provide an estimate of the number of enforcement units required to effectively enforce a given number of locations or the number of locations that can be effectively enforced using a fixed number of enforcement units ([Tay and de Barros, 2009](#)).

It should be noted that distance has both an adaptive and maladaptive effect. This is especially true for highly visible enforcement. Some drivers will begin to change their behavior, such as slowing down, before they reach the enforcement point or location and will continue to drive slower for some distance after they passed the point of enforcement, especially for visible mobile enforcement units. These pre- and postdistance halos are critical parameters when considering the number of enforcement locations needed to effectively cover a given geographical area.

Learning Theory and Enforcement Scheduling

Theoretically, focusing the limited enforcement resources at a smaller number of locations will increase the likelihood of punishment for a smaller group of drivers, but decreases the likelihood for a larger group of drivers. On the other hand, spreading out the enforcement to a larger number of locations will increase the general deterrence but reduce the specific deterrence.

In practice, many road safety professionals have advocated that enforcement should be random and unpredictable, which is neither based on any behavioral theory nor any empirical evidence. Part of this misconception arises due to misconstruing enforcement as a negative reinforcement which is the removal of an undesirable thing from the person when he/she behaves in the desired manner. Negative reinforcement rarely occurs in law traffic enforcement. On the other hand, punishment is much more prevalent in traffic enforcement. Positive punishment which is the imposition of an undesirable thing to discourage bad behavior is quite common, including the imposition of demerit points, monetary fine or detention. Negative punishment which is the removal of a desirable thing to deter bad behavior, such as license revocation, also occurs in traffic enforcement although to a lesser degree. The empirical evidence shows that whereas negative reinforcement is more effective when administered intermittently (variable ratio), punishment is more effective when administered continuously. Hence, the practice of scheduling enforcement to be random and unpredictable should be taken with caution. The empirical evidence thus far suggested that focusing enforcement in smaller number of locations is more effective than randomly scheduling enforcement among a larger number of locations ([Tay and de Barros, 2011](#)).

Figure 2 Risk propensity and violations under uncertainty.

Economic Theory of Choice under Uncertainty

In economics, a risk-taking consumer is assumed to always choose the higher risk alternative with a greater reward than and a less risky alternative with a smaller reward, as shown in Fig. 2. If traffic enforcement is uncertain, then a risk-taking consumer will always choose to disobey the traffic law because the expected utility or satisfaction from not obeying the law is higher than obeying the law. If traffic law enforcement efforts are targeted at high risk-taking drivers, then it should not be uncertain and unpredictable. However, if the enforcement efforts are targeted at the low-moderate risk drivers, then it should be unpredictable.

Deterrence Production Frontier

Since enforcement resources are limited, it is vital to optimize the mix between general and specific deterrence to maximize the safety or the overall deterrence effect. Many different strategies and experiments have been proposed, implemented and/or evaluated, with differing results. This is not surprising since the effectiveness of the strategy will depend on many operational factors, including the type of behavior, risk profile of the user population, enforcement method, enforcement time and location, and the overall level of enforcement or amount of resources used, which differ substantially across different studies.

Theoretically, different enforcement strategies will produce different combinations of general and specific deterrence. As an example, consider the deployment of road safety cameras, and for simplicity, consider two operational aspects of deployment: overttness and location. Safety cameras can be deployed overtly and visibility at high visibility or high traffic locations to maximize general deterrence or covertly at high violation locations to maximize specific deterrence. As shown in Fig. 3, given a fixed amount of enforcement resources, there are many different combinations of overt/covert and high visibility/high violation combinations that can be used. Some of the combinations are expected to maximize the amount of deterrence produced and will form the deterrence production frontier while other less effective strategies will be located inside the frontier. An overall safety or deterrence level higher than the frontier level can only be achieved by increasing the amount of enforcement resources.

To optimize the allocation of scarce law enforcement resources, only those combinations on or near the frontier should be considered. The best combination to use will depend on the profile of the road user population. More importantly, more research needs to be conducted to identify the operational factors influencing the effectiveness of different enforcement strategies as well as quantifying the relative effects of the different operational factors. Till date, very little research has been conducted to directly compared the different strategies and fewer have attempted to estimate the deterrence production function or safety production function for traffic law enforcement.

Figure 3 Deterrence production frontier.

Conclusion

Traffic law enforcement is one of the three pillars of road safety. The experience from around the world has shown that it is an effective method to reduce traffic violations and crashes. However, the design and implementation of the traffic strategies in different jurisdictions varies considerably. This article provides researchers and relevant authorities with a summary of some theories and models that can be used to design and evaluate traffic law enforcement programs.

Introduction

Travel is central to almost all human activities. Everyday travel includes journeys at short distances to school or work, shopping outlets, various other facilities, and visits to relatives or friends. Less frequent longer journeys are made to holiday destinations away from home. Longer journeys are also made for business. The benefits to individuals and society are huge; however, the benefits need to be balanced against costs of environmental damages, accidents, and unproductive time.

Purpose of travel, travel time, and experiences during travel have bearings on the two questions raised in the following: What makes everyday travel satisfying or dissatisfying, and how does satisfaction or dissatisfaction with everyday travel influence well-being? In order to answer the first question, research has focused on the central features of travel illustrated in Fig. 1. Addressing the second question, research has implemented knowledge and measurement methods developed in well-being research.

The purpose of destination-oriented travel is associated with need, obligation, or desire to engage in some activity at the destination, either work, sustenance, or leisure, corresponding to the common classification in transport policymaking and planning.

When populations of interconnected people in urban areas grew and spread spatially, faster modes were necessary to not increase total travel times. Motorized travel resulted in longer travel distances but only marginally longer travel times. Walking differs from motorized travel in being slower and hence is referred to as a slow travel mode. Cycling is another slow travel mode. Together walking and cycling are labeled active travel modes since they in general require more physical activity than passive motorized travel.

Motorized travel modes are private or public. In private transportation, vehicles are not shared or shared with relatives or friends, in public transportation vehicles are primarily shared with strangers. This results in different forms of social interaction. Another difference is the degree to which different modes restrict travel in time and space, with consequences for congestions, accident risks, and delays.

Satisfaction With Travel

A traditional approach is to assess satisfaction with everyday travel based on utility-maximization theory. According to this theory, choices people make that maximize utility result in satisfaction with the outcome of their choices. Satisfaction with travel is therefore derived from observed choices. However, since the outcome of a chosen alternative is not always experienced to be satisfying, the assumed correspondence between utility of choice outcomes and satisfaction has been challenged (DeVos et al., 2016). Several complementary methods of self-report ratings of satisfaction with travel have therefore been developed and used, but few have been subject to adequate psychometric assessments. An exception is the multi-item Satisfaction with Travel Scale (STS) validated and used in several studies.

The STS retrospectively measure satisfaction with any form of travel. Analogous to self-report measures of well-being (see next section), it combines a cognitive-evaluation dimension (e.g., ratings on a scale from high to low travel quality) with two dimensions that assess mood (a less transient feeling state) during travel. The theoretical basis for the mood dimensions is the affect circumplex defined by the two orthogonal principal dimensions pleasure versus displeasure and activation (arousal) versus deactivation. Items

Figure 1 A classification of travel features. Source: Adapted from Gärling et al. (2019), with permission.

in the STS consist of validated rating scales that tap two dimensions oblique to the principal dimensions of the affect grid, one ranging from unpleasant deactivation to pleasant activation (e.g., ratings on a scale from tired to alert), and the other ranging from pleasant deactivation to unpleasant activation (e.g., ratings on a scale from calm to stressed). The three STS dimensions are distinct constructs positively correlated with each other and subsumed to a latent higher-order construct of overall satisfaction with travel. Measures of the dimensions have acceptable reliability, their relationships are invariant across primary travel modes, and they satisfactorily discriminate between the travel modes.

Although the object of measurements of satisfaction may be unspecified travel, it is more commonly satisfaction with a specified class of journeys or journey, or a specified travel mode for a specified class of journeys. The most frequent object is satisfaction with commutes to and from work by different travel modes (Chatterjee et al., 2020). Purpose, travel time, and experiences during travel are factors associated with travel mode that influence satisfaction with travel. In direct comparisons of travel modes satisfaction with the active commute modes of walking and cycling is higher than satisfaction with the passive commute mode car use, and satisfaction with car use is higher than satisfaction with the other passive commute mode public transport use. In the following, we first focus on aspects that are partly independent of travel mode, then aspects that are specific for the different travel modes.

Independent of Travel Mode

Some travel purposes have direct relationship to well-being, and such relationships carry over to satisfaction with travel for these purposes. An example is that satisfaction with travel to leisure destinations is higher than satisfaction with travel to work.

Longer travel times due to slow speed, long distances, interchanges, or delays decreases satisfaction with travel, and sometimes also too short travel times decrease satisfaction.

Satisfaction with travel is influenced by traveler characteristics. One is favorable or unfavorable pretravel attitude. Another example is that satisfaction increases with age.

Private Motorized Travel Modes

The spread of affluence made cars affordable to most people. As a result of owning a car, people could lead a life with which they were more satisfied, frequently preferring to live in low-density suburbs further away from their downtown workplace, occupying single-family homes with a garden. The downside is that car commuting to and from work increases accident risk, is stressful or boring, and time consuming.

The way the society today is spatially organized requires travel to different places for different purposes. Current travel demand thus goes beyond the home-to-work journey on weekdays, including as it does frequent multipurpose and multistop trips at different times during all week. For trips exceeding walking distance, the versatile car is then the travel mode that increases satisfaction with travel more than other modes. That the car is usually the fastest travel mode increases satisfaction further.

The status and identity associated with being a car owner is another source of satisfaction that has roots in the very early days of the car. Today the ubiquity of the car has led to it being perceived as an everyday tool, and anyone not owning a car is perceived as being less well-off.

The purpose for using a car is sometimes not activity participation; car use is thus not purely a demand derived from the purpose of travel. This is the case when people travel for the sake of traveling or travel to a destination via a more scenic route. Affective (e.g., enjoyment) and symbolic (e.g., showing others) factors are important additional motives for car use, in particular for men and younger people. Excess driving furthermore results from valuing driving itself. Yet, driving is also sometimes stressful or boring.

The various benefits of the car that have led to its frequent use may result in the development of a car-use habit. Important conditions for the development of a habitual behavior is that a person is able and motivated to repeat the behavior, and that the behavior is rewarded such that it is repeated a sufficient number of times in a stable context. These conditions frequently apply to car use. A car-use habit implies that information processing is changed such that the intention to travel to a specified destination automatically activates a car choice.

Table 1 Quality attributes in public transport

Category	Attribute	Definition
Perceived	Comfort	How comfortable the journey is regarding access to seating, noise levels, driver handling, and air conditioning
	Safety/Security	How safe from traffic accidents passengers feel during the journey as well as personal safety
	Convenience	How simple the service is to use and how much it adds to ease of mobility.
Physical	Aesthetics	Aesthetic appeal of vehicles, stations, and wait areas
	Reliability	How closely the actual service matches the route timetable
	Frequency	How frequently the service operates during different hours
	Speed	The time spent traveling from origin to destination
	Accessibility	The degree to which the service is available to as many as possible
	Price	The monetary cost of travel
	Ease of transfers/interchanges	How simple transport connections are including wait times
	Vehicle conditions	The physical and mechanical conditions of vehicles including frequency of breakdowns
	Information provision	How accurate the information is about routes and interchanges

Public Motorized Travel Modes

Historically, public transport (the term “public transport” is predominantly used in Europe, Japan, and Australia, the interchangeable terms “mass transit” or “public transit” are used in North America and Southeast Asia (primarily in China, Hong Kong, and Singapore)) services (railways, tramways, and buses) originated in Europe in connection with the 19th century industrialization, urbanization, and separation of residences from workplaces. The industrialization both increased demand for fast mass transportation at a large scale of people and goods as well as providing the technical and economic means of meeting this demand.

Public transport is a more economical and environmentally friendly motorized travel mode than the car. However, at least in suburban and rural areas, it is less versatile and slower. These are main reasons why satisfaction with public transport is lower than satisfaction with car transport. In densely populated urban areas, public transport (in particular metro and commuter trains) is still attractive.

A number of attributes of public transport services that increase user satisfaction have been identified. A list of these attributes is shown in **Table 1**. Perceived attributes refer to users’ experiences directly measured by observing their responses. If, for instance, seats are replaced in vehicles to increase comfort, this may be assessed by on-board interviews. Physical attributes are measured without involvement of users. For instance, the effect of a revised timetable may be assessed by measures of punctuality, assuming it would reflect changes in user perceptions of reliability.

Satisfaction with travel does not solely depend on cognitive evaluations of features. Critical incidents generally defined as an event that stands out from what is normal by being perceived to be either negative or positive but the definition may include additional, more specific criteria depending on research field) during travel appear to influence satisfaction, partly due to their emotional impacts. In public transport critical incidents are primarily negative, for instance inappropriate treatment by employees, lack of punctuality, or crowding.

In many places around the world, great effort has been made to improve public transport services. This has paid off in increased patronage. Success factors are active collaboration between different stakeholders, high-quality bus systems, visual and distinct company brands, and integration of travel modes.

Nonmotorized Travel Modes

Walking and cycling declined when motorized travel increased. An upsurge has however been observed during recent years, possibly with the exception for children, low-income earners, and the elderly. Satisfaction with travel is also high for nonmotorized travel modes. Although traveler self-selection or unavailability of motorized alternatives are possible reasons, intrinsic attributes of the active travel modes are important. One factor standing out is that nonmotorized travel helps people engage in physical activity that they believe have positive health effects. Satisfaction is also influenced by other factors, including experienced excitement and variation in the environment, company of others, enjoyment of the activity (walking or cycling) itself, scenery, and weather.

Combined Travel Modes

Many journeys consist of several stages. Walking to and from the bus stop, train station, or car park before and after using the primary travel mode are common examples. Public transport journeys may also require changes from bus to train or from one bus or train line to another. How is satisfaction with the journey related to satisfaction with the stages of the journey? Is overall satisfaction influenced by satisfaction with each stage or do stages with high and low satisfaction have more influence? Does satisfaction with the end of the journey (reaching the destination) have a stronger influence? For commutes to and from work, integration is made by

averaging satisfaction with the stages, weighted by their duration. This may be different for journeys that are less routine. Duration-weighting is still consistent with that satisfaction is influenced by travel time.

The Relationship to Well-Being

Well-being has in the past frequently been equated with material living standard, indicated by, for instance, income or GDP per capita. In recent years the focus has, as recommended by the United Nations and OECD, changed to subjective experiences of well-being, referred to as life satisfaction and emotional well-being. In particular in wealthy countries, the roles of other than material conditions are increasingly becoming recognized. In addition to socioeconomic factors, social relations, health, and personality traits are important determinants. Furthermore, both life satisfaction and emotional well-being are strongly associated with the fulfillment of human needs. Satisfaction with everyday activities also play important roles. Travel enables people to engage in out-of-home activities that may increase their life satisfaction, at the same time as travel itself is an everyday activity that may influence emotional well-being (Ettema et al., 2010).

Travel-Related Emotional Well-Being

Emotional well-being is measured retrospectively by asking people to report the frequency (or duration) and intensity of positive and negative feelings recalled for a specified time interval. The measure captures the prevailing mood as well as transient feelings in response to external events. In the Day Reconstruction Method (DRM) people are asked to recall important activities during a preceding day and indicate for each activity how they felt when performing it. Still another method is to ask people in real time to report how they feel at the moment. If reported retrospectively, or momentarily at several points in time, a measure of emotional well-being is constructed as the difference between the frequency of positive and negative feelings.

Positive and negative critical incidents during travel influence emotional well-being measured retrospectively by the mood scales in the STS. Users of cars and active travel modes have more positive moods than users of public transport. Longer travel times make public transport users more bored and less relaxed. Activities performed during travel may counteract negative mood effects.

As assessed by the DRM, negative feelings are associated with commuting. This is consistent with that commuting causes stress, as revealed by performance measures. But everyday travel only seems to account for a few percent of the variance in aggregated measures of daily mood. Satisfaction with travel still has direct effects on weekly mood as well as indirect effects through feelings associated with frequent travel-dependent out-of-home activities during the week.

Spill-Over Effects on Emotional Well-Being

Long car commutes have stress after-effects which negatively affect activities at work and home. Yet, momentary measures of mood before and after morning commutes to work, by active and passive travel modes, indicate that mood is relatively stable. Neither do changes in mood after travel carry over to mood at the workplace.

Travel-Related Life Satisfaction

Life satisfaction is usually assessed by means of cognitive judgments, either a single judgment on a ladder ranging from 0 (worst possible life) to 10 (best possible life), or a multi-item measure referred to as the Satisfaction with Life Scale including questions such as "I am satisfied with my life" and "in most ways my life is close to my ideal".

Commuting has potentially negative effects because it limits time for physical and social leisure activities that are important for life satisfaction. Restricting travel may also cause social exclusion which has a strong negative association with life satisfaction.

Other travel than work commutes have direct effects on life satisfaction, either because travel is in itself a valued activity or because travel enables other valued activities (e.g., social visits).

Conclusions

Recent years have seen an accumulation of knowledge of what influences satisfaction with destination-oriented everyday travel and how it influences emotional well-being and life satisfaction. Perhaps the most important contribution to date is still the development and validation of feasible methods for measuring satisfaction and well-being, which otherwise would appear to be elusive constructs and therefore neglected in transport planning. However, this does not imply that methods that for decades has been the core in previous research and application should be replaced. Rather, new and old methods are possible to combine to the benefit of an increasing methodological sophistication and rigor.

Additional research is needed to further develop online methods for measuring satisfaction with travel. The aim should be to increase knowledge of how satisfaction is related to features of travel. This is needed for improving design and management of transportation systems such that satisfaction with travel services increases. Everyday travel (e.g., commuting) is not in general an activity that in itself promotes emotional well-being and life satisfaction. Increasing travel-related satisfaction is still essential since it would reduce the negative consequences of everyday travel for emotional well-being and life satisfaction.

Introduction

Electromobility is considered a key technology for sustainable mobility in the future. Currently in many countries the number of electric powered cars is increasing and infrastructure for charging is increasingly being developed. The adoption of electric powered cars essentially depends not only on technological progress like battery technology or carbon-light weight, but largely on psychological features such as acceptance that, aside from pricing, mostly depends on range and charging infrastructure.

Besides electric powered cars, electric bikes (e-bikes or pedelecs) are becoming a viable option for transport, particularly in urban areas. Psychological research is addressing questions of mode choice, route selection, and safety due to higher vehicle speeds and weights.

History

The history of electric powered vehicles began in 1881 when Gustave Trouvé presented the first e-car, the Trouvé Tricycle, a couple years ahead of Carl Benz's combustion engine powered car. The first German e-vehicle was the "Flockenwagen," introduced in 1888, which was based on a four-wheel carriage and is considered the first electric powered passenger car. Around 1900 many more electric powered cars existed than those with an integrated combustion engine (ICE). For example, it is estimated that more than 90% of cabs in New York were electric powered. Famous examples are the "Lohner-Porsche" (1900), "Columbia" (1904), and "Siemens Viktoria" (1905). The Lohner-Porsche was also the first example of a hybrid electric vehicle (HEV) that used four hub-mounted electric motors to directly control the wheels. The situation changed in the first half of the 20th century, particularly after World War I. The number of ICE cars steadily increased due to an extended range and easier handling, whereas the number of electric powered cars diminished. In the late 20th century, ICE vehicles were vastly more common. Only few concept cars were around, like the "BMW 1602" (1969) or the "VW Citystromer" (1982). In the first decade of the 21st century, the situation completely changed. Due to problems with air-pollution, noise, and climate change in general e-mobility awoke from hibernation. Regions like California sharply restricted the emission of CO₂ and forced manufacturers to develop alternative engines for vehicles. Nowadays, all major manufactures offer a broad variety of different EV types.

In 2010, the European Union had around 1500 newly registered e-cars. In 2019, this number increased to around 463,000, which is about 300-times more, but still significantly fewer than the number of newly registered cars with traditional ICE. World-wide, e-car registration in 2019 is estimated to be around 2,200,000 (up from around 200,000 in 2013), according to the German Association of the Automotive Industry (VDA). It is further estimated that the number of electric models available will surpass 200 in 2021 and that European EV production will reach about 4 million vehicles by 2025.

In 2010, about 300 charging stations were in use in Germany. Ten years later, around 30,000 stations are working. This is around 100 times more with a growth rate increasing exponentially.

What is it? Terminology

An electric car (e-car or e-vehicle, EV) or battery electric vehicle (BEV) is a vehicle propelled by one or more electric motors, using energy stored in rechargeable batteries.

A hybrid electric vehicle (HEV) is a vehicle containing an electric drive train combined with an ICE. A famous and bestselling example is the “Toyota Prius.”

A plug-in-hybrid electric vehicle (PHEV) contains a battery that can be recharged by being plugging into an external source of electric power or by an on-board engine or generator. A famous example is the “Toyota Prius PHV.”

Range-extended electric vehicles (REEV) or extended-range electric vehicles (EREV) are vehicles that include an auxiliary power unit (APU) known as range extender, but are mostly an ICE. The unit drives an electric generator which charges the battery to increase the vehicle’s range.

Recuperation or regenerative braking is a procedure to convert kinetic energy into electric power to be used immediately or later by storing the energy in the battery. It is an important mechanism to extend the range and is a main characteristic of EVs.

An electric bicycle (e-bike) is a bicycle with an integrated electric motor that supports the driver up to a certain speed. Regarding performance and driver support, there is a wide variety of types ranging from low-powered e-bikes, called pedelec (PEDal ELectric Cycle, usually up to 25 km/h with up to 0.25 kW power) to S-pedelecs (up to 45 km/h), which are classified differently from country to country (bicycle, moped, motor-scooter).

Psychological Issues

The impact of electromobility on traffic and transport with regard to acceptance and purchase decisions highly depends on psychological factors. In several user studies, most including predominately “early adopters” (specific sample—middle-aged men, high education, high income) or rather inexperienced users—the following topics were identified as most important:

Range Stress

Less range, compared to ICE cars, was considered an essential disadvantage of EVs more than 100 years ago and is still a main barrier towards BEV adoption (Li et al., 2017). In the last 10 years, the increased battery capacity has been a major research focus resulting in cars on the market currently that have a range of around 500 km. However, this is still less than a comparable conventional car. A second issue is charging infrastructure and duration. Compared to a conventional gas refill stop, charging batteries, even with fast-charging technology, still takes much longer. Also, the number of charging stations is still far below the number of regular gas-stations. However, large field studies (e.g., The MINI-E studies, Krems et al., 2011; Pearre et al., 2011) show that around 95% of all trips are shorter than 200 km and that users were satisfied with a range of around 160 km. Franke et al. (2012, 2017) distinguish between different range levels. “Cycle range” is the “objective” trip length given a certain state-of-charge (SOC) of the batteries. “Competent range” is the range possible if users operate the vehicle while maximizing energy saving. “Performant range” refers to the actual driver behavior, which is influenced by (lack of) skills, habits, and motivation. “Comfortable range” refers to the SOC percentage considered necessary for drivers to feel comfortable. Meanwhile in psychological research, the term “range anxiety” was shifted to “range stress,” which captures the driver’s psychological status in a much more appropriate way. In their model, Franke et al. (2012) assume that recognizing a low remaining range for a certain trip constitutes a conflict between available resources and eternal demands. This person–environment imbalance bears similarities with common stress definitions, particularly with the transaction theory of stress (Lazarus and Folkman, 1984). This model emphasizes that reducing stressors (e.g., increasing range) is only one coping strategy supplemented by individual appraisal processes and social support. Range is primarily a psychological barrier and must be considered together with mere increasing nominal battery capacity.

Eco-Driving

With regard to the limited range, energy saving strategies during driving (eco-driving strategies) are specifically relevant when driving BEVs compared to conventional vehicles. In terms of the range model (Franke et al., 2012), eco-driving strategies are considered appropriate to cope with range stress (i.e., in low on charge situations) and therefore potentially reduce negative feelings regarding limited range (Rauh et al., 2017). Eco-driving strategies comprise aspects of route choice (e.g., elevation profile), driving maneuvers (e.g., moderate acceleration) and driving-related actions such as the usage of auxiliary functions (e.g., air conditioning). Although most eco-driving strategies for BEVs are similar to those known from conventional vehicles, there are some EV-specifics, most relevant amongst them the optimal usage of regenerative braking (Helmbrecht et al., 2014; Jensen et al., 2020). Drivers’ growing experience has been studied to gain knowledge on BEV eco-driving strategies (Neumann et al., 2015) and their implementation in critical range situations (Günther et al., 2019). Additionally, experiencing a critical range situation combined with informing drivers about efficient eco-driving strategies has shown to improve even inexperienced BEV drivers’ eco-driving knowledge and acceptance (Günther et al., 2017). Similar to other pro-environmental behaviors, motivational aspects influence eco-driving (Neumann, 2016). Therefore, effective interventions such as persuasive elements in in-vehicle instrumentation (Günther et al., 2020) could enhance comfortable range and also strengthen the environmental benefit of EVs.

Noise

Compared to ICE vehicles, the BEV's engine noise emission is quite low resulting in "silent" driving at least during low speeds (<30 kph), where the tyre noise emission is negligible. This lack of noise is described twofold in the literature. On the one hand, BEV drivers and passengers clearly appreciated it, enhancing their driving pleasure (Bühler et al., 2014; Cocron et al., 2010; Daramy-Williams et al., 2019). Moreover, it offers a potential environmental benefit by reducing noise pollution, for instance in big cities (del Carmen Pardo-Ferreira et al., 2020). On the other hand the lack of noise emission and the corresponding later perception of BEVs at low speeds compared to conventional vehicles (Stelling-Kończak et al., 2015) has been discussed as a potential hazard, especially for vulnerable road users (VRUs; e.g., pedestrians or cyclists). Focusing on driving pleasure, user studies revealed that the lack of noise is considered as one of the main advantages of BEVs from a driver perspective (Bühler et al., 2014; Cocron et al., 2010), and, in turn, could even increase the chances for BEV acceptance (Bühler et al., 2014). Furthermore, experience effects show that initially positive ratings of silent driving even increased after BEV driving for a certain time period (Bühler et al., 2014; Carroll, 2010). Addressing safety concerns, several studies showed a relatively low perceived risk of traffic incidents reported by BEV drivers, which decreased after BEV driving for a longer period (Cocron and Krems, 2013). Additionally, experienced BEV drivers reported to be aware of potential hazards and therefore adopted more cautious driving styles (Cocron and Krems, 2013). There are also hints that inexperienced BEV drivers show such awareness and compensatory behavior (Cocron et al., 2014). Looking at research analyzing crash statistics, it is still unclear whether there is a higher incident rate for electric compared to conventional vehicles with VRU involvement, mainly due to missing exposure data and the few registered accidents (Stelling-Kończak et al., 2015; Pardo-Ferreira, 2020). Early in the discussion about the safety issue of low noise emission, additional vehicle sounds, so called Acoustic Vehicle Alerting Systems (AVAS), have been proposed as possible solution. Although drivers do not view this strategy as necessary or appreciated (Cocron and Krems, 2013; del Carmen Pardo-Ferreira et al., 2020), many countries (e.g., Japan, US, EU; e.g., European Commission, 2014) have introduced respective regulations demanding the implementation of additional sound to BEVs. Analyzing possible positive and negative AVAS consequences will certainly be a challenge for upcoming research on BEV acoustics.

Acceptance

Searching for strategies to enhance BEV adoption and reduce subjective barriers in this regard, BEV acceptance has been extensively investigated throughout the last two decades (Coffman et al., 2017; Li et al., 2017; Rezvani et al., 2015). According to Schade and Schlag (2003) acceptance is defined by "respondents' attitudes including their behavioral reactions after the introduction of a measure" (p. 47). Following this definition, BEV acceptance involves an attitudinal as well as a behavioral component, both of which have been addressed in research on this topic (compare also Li et al., 2017; Rezvani et al., 2015). A common theoretical background investigating BEV acceptance, including the willingness to buy such a vehicle, is provided by the theory of planned behavior (TPB; Ajzen, 1991), often extended by further factors such as experiencing BEVs or the assessment of BEV features (e.g., Li et al., 2017; Moons and De Pelsmacker, 2012; Rezvani et al., 2015; Schmalfuß et al., 2017;). In addition, a variety of psychological constructs and theories exist providing the basis for consumer BEV adoption research (see, e.g., Li et al., 2017; Rezvani et al., 2015 for further discussion). Examples describing and predicting BEV adoption and related intentions include the diffusion of innovation theory (Rogers, 2010; e.g., Peters and Dütschke, 2014), normative theories (e.g., value-belief-norm; Stern, 2000) but also theories associated with symbols and self-identity (e.g., Noppers et al., 2014; Schuitema et al., 2013). Reviewing the literature on BEV acceptance, Li et al. (2017) regard attitudes towards BEVs to be the most effective predictor of BEV acceptance. In addition, other psychological aspects like experiencing BEV features (e.g., low noise emission, acceleration, regenerative braking) and consumers' expectations as well as symbolic attributes have shown to be important factors influencing BEV acceptance (Li et al., 2017; Rezvani et al., 2015). Provision of direct BEV experience appeared to considerably impact the assessment of BEV features as well as attitudes (e.g., Li et al., 2017; Schmalfuß et al., 2017). This finding underlines the importance of the provision of hands-on experience for studying BEV acceptance and simultaneously narrows the external validity of studies with participants who had never previously experienced a BEV and its features, such as surveys with inexperienced participants (compare also Coffman et al., 2017; Li et al., 2017). The BEV market penetration is still far behind expectations and targets, possibly because of the limited driving range combined with potentially long charging durations as well as battery costs and the relatively high purchase price as the most important barriers (Coffman et al., 2017; Li et al., 2017; Liao et al., 2017). Additionally, factors like consumer characteristics (e.g., gender, age, education) as well as social norms or values have been seen to influence BEV acceptance (Coffman et al., 2017; Li et al., 2017).

E-Bikes: Usage, Safety, and Mode Choice

In recent years, e-bikes have become increasingly popular on our roads. In Germany, more than a third of sold bicycles are equipped with an electric motor. Across Europe, the number of sold e-bikes increased from 0.5 million in 2009 to 3.6 million in 2018 (Statista Research Department, 2020). Pedelects can help to reduce traffic congestion in cities and air-pollutions. Further, they are a way to obtain physical exercise for many people. Compared to conventional bicycles, pedelecs offer the opportunity to maintain speed with less effort regardless of hilly routes, individual physical fitness or trip length, therefore overcoming one of the main barriers of conventional bicycles (Fishman and Cherry, 2016). Due to their electric support, e-bikes are especially attractive for older age groups—in Germany, for example, half of all pedelec trips are made by persons 60 years and older (Nobis and Kuhnimhof, 2018).

This has mainly positive impacts, such as enhancing physical fitness and activity in older age, but also increases the risk of higher accident rates. Gehlert et al. (2018) found higher proportions of elderly involved in pedelec compared to bicycle accidents. The authors also observed more pedelec accidents involving inappropriate speeds, specifically for elderly cyclists. In general, e-bike accidents appeared to be more severe (more fatalities and severe injuries). Comparing conventional and e-bike usage, Schleinitz et al. (2017) found similar trip lengths and purposes for both vehicle types. Furthermore, e-bikes are driven only slightly faster than bicycles, with the exception of S-pedelecs, which are driven at considerably higher speeds. E-bikes offer a substantial environmental benefit—depending on country and study, many car or bus trips were replaced by riding an e-bike (Fishman and Cherry, 2016). Cargo e-bikes, enabling the user to carry large and heavy weights, are one solution discussed to reduce air pollution caused by private transport. In this regard, a Norwegian study showed decreased car use and increased cycling trips per day, as well as increased trip distances for families equipped with cargo e-bikes compared to a control group (Bjørnarå et al., 2019). Currently, some initiatives exist to establish sharing concepts for cargo e-bikes in cities to make this promising (but expensive) travel mode available to a large user group and thus reach their full potential.

Summary

In times of climate change, electric mobility is seen as one promising solution to reduce CO₂-emissions in the traffic sector given alternative energy usage as well as appropriate production and recycling conditions. The term electromobility comprises various vehicles propelled by electric drive — ranging from hybrid and fully electric cars to busses as well as e-bikes and cargo e-bikes — and includes infrastructure necessary for charging and managing the vehicles.

Initially, psychological research mainly concentrated on electric cars, focusing on BEV acceptance and users' interaction with specific features such as limited range, noise-reduced driving and regenerative braking. Research has shown a complex set of factors and interactions impacting the BEV adoption process ranging from BEV-related to individual and societal facets, which might be met by an equally comprehensive set of actions addressing many of the specific facets to push this process, if intended.

During the past few years, electric two-wheelers have become increasingly popular. Given their low weight and the potential to replace the car as a mode of transport, these vehicles even enhance the environmental benefit and additionally bear the potential of a more active lifestyle. Given their specifics (e.g., predominantly elderly cyclists, different speed profile, high acquisition costs—at least for cargo e-bikes), research, and policy are required to provide specific knowledge and implement appropriate measures to take the chance on this environmental friendly mode of transportation.

Introduction

Shared mobility services such as ridesourcing, carsharing, and micromobility vehicle (e.g., bicycle and e-scooter) sharing are reshaping many aspects of our transportation system. In the last decade, large private sector investments met with rapid growth of technological innovation. Technology like location-based smartphone services and onboard vehicle telematics have allowed previous low-tech models of shared mobility to scale to billions of trips in a short period of time. Low tech models (e.g., conventional taxis, free-floating bikesharing) have been replaced or forced to adapt to the emergence of new competitors. Cities have been forced to revisit how they operate and prioritize the public right of way. The public has adapted to changing norms on sharing space, resources, and information. The rapid change in attitudes and perceptions of shared mobility options is becoming more understood as researchers have conducted both quantitative and qualitative studies focusing on the adoption of different sharing models. Some shared mobility services appear to be more popular than other, seemingly similar, technologies. Shared scooters, for example, have a much higher adoption rate compared to bikesharing. In their first year of launch, there were 38.5 million scooter trips in the United States in 2018, about the same number as bikesharing trips that had been growing annually for a decade ([National Association of City Transportation Officials, 2019](#)). The rate of adoption of shared scooters was faster than the rate of adoption of ridesourcing ([Bruce, 2018](#)). While this shift may be driven largely by technological advancements and innovative business models, how people perceive these shared mobility options plays an important role. This chapter presents a narrative on this dynamic evolution of perceptions and attitudes and summarizes what is known and unknown about how consumers perceive this evolving portfolio of transportation services. It also describes how different models and technologies have evolved and comments on what this may mean for transportation and society in the future. We will start this chapter by understanding what shared mobility is.

What is Shared Mobility?

Shared mobility, or shared-use mobility systems, are broadly defined as shared used of travel modes such as a vehicle or a bicycle that provide users with short-term access on an as-needed basis ([SAE International, 2018](#)). This definition includes many well-known shared modes such conventional taxis and public transportation, but also maturing models like bikesharing and carsharing and emerging models like e-scooter sharing. Collectively, transportation systems that fall under shared mobility are often grouped under mobility on demand (MOD) or mobility as a service (MaaS) categories. This contrasts with recent transportation systems that are either public (e.g., a public-sector-owned system providing transportation services through transit agencies) or private (e.g., private automobile ownership). MaaS frameworks break from those compartments, where the public sector, private sector, or individuals can provide market-driven transportation services through shared mobility platforms that are often enabled by smartphone applications or other technology to overcome barriers to previous shared mobility schemes.

Shared mobility terminology is evolving rapidly. The SAE International Standard J3163 ([SAE International, 2018](#)) aims to clarify terminology through standards development. From a consumer perspective, that document broadly describes shared mobility in three dimensions: (1) the travel modes, (2) the enabling mobility applications, and (3) the service and operational models. The travel modes refer to a variety of shared mobility options such as motor vehicles, bicycles, and e-scooters that are available to meet diverse mobility needs. The enabling mobility applications are smartphone applications that provide users with travel information (e.g., navigation, schedule) and/or assistance in using shared mobility services if needed. For example, users can check the availability of for-hire taxis in the area and reserve one through such applications. Last, differences in service and operational models capture the variations of the relationship between a user and the shared mobility service provider. For example, such relationship can be membership-based, for-hire, peer-to-peer (P2P), or come in other forms.

From an attitude and perception perspective, different models have different potential barriers. For example, some modes require interaction with a driver (who might be a professional driver or a contract driver, e.g., taxi or ridesourcing), some also require

Figure 1 Classification of selected shared mobility travel modes. *Source: Adapted from Shared-Use Mobility Center and SAE International.*

interaction with passengers (e.g., pooled ridesourcing), and others require no interaction with others (e.g., bikesharing and carsharing). Shared mobility modes can be used concurrently by users sharing rides at the same time, or they can be used sequentially by users taking turns sharing vehicles (Shared-Use Mobility Center, 2020). Following this dichotomy in Fig. 1 we categorize the most important shared mobility modes. Ridesourcing bridges concurrent and sequential shared mobility models since ridesourcing can be pooled. Two of the concurrent modes, ridesharing (e.g., carpool) and conventional public transit are well documented in the literature. This chapter focuses on attitudes and perceptions of contemporary and emergent shared mobility modes; carsharing, ridesourcing, bikesharing, and scooter sharing.

Of these four emergent shared mobility modes, there are common characteristics that tie together their users. Shared mobility users tend to be younger, more often in carless or car-light households, and have higher incomes and education levels than the general population (Alonso-Almeida, 2019; Martin and Shaheen, 2011; Sikder, 2019; ter Schure et al., 2012). Some of that rider base may be drawn from the geographic distribution of services. Shared mode operators and regulators often make deliberate efforts to expand services to improve equitable access (Howland et al., 2017; Pan et al., 2020).

Carsharing

Carsharing is among the pioneers in the shared mobility industry. A carsharing program provides a group of users the access to a fleet of vehicles whose parking, insurance, fuel, and maintenance are usually covered by the service provider (SAE International, 2018). Depending on where users are instructed to return the shared vehicle, a carsharing system can be categorized as a one-way (also known as free-floating), round-trip, or a hybrid system. For example, a round-trip system requires users to return the vehicle to the same place where it is picked up and the user is responsible for the vehicle for the entire duration of their round-trip. A one-way system allows users to end their reservation wherever they end a (one-way) trip. One-way systems support more one-way trips like transit tours where carsharing supports the first- or last-mile. Variations of carsharing models also come from different types of ownership models of the shared vehicles. In cases where the shared vehicles are owned by some users and shared among other users within the system, known as a peer-to-peer (P2P) carsharing model. The P2P model exists in other shared mobility systems as well and we will revisit this concept in the following sections. It is of important to acknowledge this difference in shared vehicle ownership as it can affect how consumers perceive and use these services.

In North America, carsharing services first emerged in residential neighborhoods before diversifying into other market segments such as university campuses (Shaheen et al., 2009). Because carsharing services provide on-demand vehicle access at a lower price compared to owning a vehicle, it can be appealing to the carless population, who are likely the early adopters and the targeted consumers of such services. Carsharing users tend to reduce their overall car miles traveled, reduce transit use, while increasing their walk and bicycling trips (Cervero et al., 2007; Martin and Shaheen, 2011).

A number of factors are known to influence mode choice and the decision to use carsharing. Among them, high cost and long travel time to an accessible shared car are barriers to grow carsharing membership (Zhou and Kockelman, 2011). In P2P carsharing, where individuals provide short term rentals of personal cars, monetary benefits are the major positive contributor, while liability issues top as the primary deterrent for both vehicle renters and owners (Ballús-Armet et al., 2014).

Burkhardt and Millard-Ball (2006) found convenience and environmental reasons are consistently the main drivers of carsharing use. More recent studies confirm those findings and also identify value-seeking and lifestyle as another two important motives of using carsharing (Schaefer, 2013). Burkhardt and Dütschke (2019) used survey data from Germany and showed that perceived compatibility with daily life is the biggest motivator for both current and potential carsharing users. However, Hartl et al. (2018) suggested that though important, the role of sustainability can be secondary and have a marginally small influence on carsharing adoption.

With rapid development in vehicle technologies and carsharing business models, perceptions and attitudes of carsharing are likely to change in the near future with uncertain implications. Electrification and automation are two recognized trends in the automobile industry. An early study among electric vehicle (EV) carsharing program in Seoul, Korea found that the EV carsharing program is unlikely to reduce car ownership (Kim et al., 2015). Yoon et al. (2017) found that Beijing respondents in a stated preference survey did not value EVs over conventional fuels. However, Lavieri et al. (2017) suggested that early adopters of shared autonomous vehicles are likely to be younger population with a higher education level, who share same similarities with the early carsharing adopters. Besides carsharing, these changes may have meaningful impacts on another vehicle-based shared mobility mode—ridesourcing.

Ridesourcing

Ridesourcing, also sometimes referred to as ridehailing, refers to a set of services that match drivers and passengers through smartphone applications for pre-arranged or on-demand travel at an agreed price (SAE International, 2018). This is different than “ridesharing” as the latter term denotes pairing services of drivers and passengers based on origins and destinations, either formally or informally. For “ridesourcing,” this relationship relies on the driver providing a commercial service to the passenger, whereas for “ridesharing” the primary purpose is to share a journey. The most representative ridesourcing services are for-hire services such as Uber and Lyft while carpooling and vanpooling are the typical forms of ridesharing.

The commercial launch of Uber in 2009, now the Silicon Valley giant, marks the beginning of the ridesourcing industry. Given its short history, the popularity of ridesourcing is remarkable as more than one in every five American have used such services (Young and Farber, 2019). Yet, with the success of ridesourcing, their impacts on the transportation system inevitably become more apparent. Pan et al. (2020) analyzed taxi and ridesourcing trips in New York City and concluded that ridesourcing services are more equitable than the traditional taxi services, and the overall equality level of the taxi industry has been improved with the advent of ridesourcing services. However, the negative impacts are also concerning. There is growing evidence that ridesourcing may increase vehicle-kilometers traveled (VKT) and congestion (Erhardt et al., 2019; Henao and Marshall, 2019; Tirachini and Gomez-Lobo, 2020), which may diminish some of the motivation from environmentally conscious travelers to use the service. These findings draw into question the environmental sustainability or congestion merits of ridesourcing.

Existing findings regarding attitudes and perceptions of ridesourcing do not largely mirror the literature on carsharing despite some similarities. Technological familiarity is an important attribute of ridesourcing users (Alemi et al., 2019; Lavieri and Bhat, 2019). However, environmental motivations do not appear to be a focus of research in ridesourcing. Rather, many studies across the globe pointed out that concerns over trust, privacy, and personal safety are the major challenges for ridesourcing adoption (Alemi et al., 2019; Lavieri and Bhat, 2019; Ma et al., 2019).

Pooled (or shared) rides provide an interesting perspective to examine this attitudes and perceptions question. By pooling riders in a shared vehicle, this branch of shared mobility service can be promising in reducing congestion, VKT, and emissions induced by individual ridesourcing trips, and even by all other vehicles on the road. However, literature suggest that pooled ride users choose such service mainly because of reasons such as time and cost savings (Alonso-Almeida, 2019), and security of a seat (Tirachini et al., 2020) other than sustainability motives. Furthermore, Alonso-Almeida (2019) pointed out that car-centric individuals highly prefer individual rides over pooled rides. This is likely associated with the long-standing images of freedom and social status that owning and driving a car may represent in some cultures. In addition, Morris et al. (2020) noted that drivers providing on-demand pooled rides are less satisfied compared to individual rides for reasons such as unfair compensation with extra work in routing, pick-ups, and drop-offs. These findings may partly explain why ridesharing (e.g., carpooling, vanpooling) and similar ideas has struggled in many markets.

The widespread adoption of ridesourcing among the younger generation is partly attributed to the use of smartphones and mobile applications. Being technology-savvy has been seen as a driving factor both in carsharing and ridesourcing adoptions. Yet, these are not the only shared mobility options that are benefiting from the fast-developing technology. Bikesharing has its own story to tell.

Bikesharing

Bikesharing is the on-demand shared mobility service that provides access of bicycles to users at a variety of locations (SAE International, 2018). There are different versions of bikesharing systems depending on types of bicycles and the service models. For example, the shared bikes can be regular bicycles, electric bicycles (e-bikes), or fleets can include a combination of both. Likewise, the bikesharing system can be station-based, dockless, or a hybrid consisting of both options. Users can either choose to pay the fares based on the number of trips taken or sign up for a membership that typically provides unlimited trips to the system with a subscription fee.

Bikesharing systems have undergone three major generational updates since the prototype in Amsterdam in 1965 (DeMaio, 2009). The contemporary model is known as the fourth generation of bikesharing. This generation features the use of mobile technology, electronic payment, and location tracking. For example, users can find, reserve and unlock a shared bike through a smart phone application, pay through debit or credit cards, and return the bike through the same app. The fourth generation

bikesharing systems started as station-based systems. For a station-based system, users can only pick up and drop off the shared bikes from an existing list of docked stations within the system boundary though the drop-off station does not need to be the same station where the shared bike is picked up. Note that this is a different concept compared to round-trip idea in carsharing discussed previously. During this period, new ideas were experimented with bikesharing. For example, [Langford et al. \(2013\)](#) piloted a bikesharing system integrating e-bikes on the University of Tennessee campus.

Early bikesharing systems were free-floating dockless systems. In the late 2000s, the industry converged on docked systems to leverage technology at the station-level and improve operational efficiency. Still, some operators pushed dockless bikesharing systems that relied heavily on on-board telematics and smartphone integration (e.g., social bicycles in the United States and call-a-bike in Germany). Yet, the most important recent game changer in the bikesharing industry to date arrived in 2015. Two Chinese start-ups MoBike and Ofo started the launch of their dockless bikesharing models around the same time in selected Chinese markets. This new model received rapid popularity and was soon exported overseas at significant scale. In the United States, for example, number of dockless bikesharing trips went up from 1.4 million in 2017, to 9 million in 2018, reflecting a jump of 4% share of bikesharing trips to almost 20% ([National Association of City Transportation Officials, 2018, 2019](#)). As the name implies, the biggest difference between a dockless bikesharing system and a station-based system is that the dockless model has no docking stations for the shared bikes. Instead, users of the system can pick up and drop off a shared bike within the system boundary in the essentially same mechanism as a free-floating carsharing system. Because there is no station hardware associated with the operation, the cost of using the dockless systems are presumably cheaper to the operator and user, which may in part contribute to their early popularity.

Due to the distinct differences between station-based and dockless bikesharing systems, the user demographics and how respective user groups perceive and use bikesharing are likely different. [Fishman \(2016\)](#) examined and summarized the literature of bikesharing before the launch of dockless models and found that the major motivation to use bikesharing is convenience for station-based bikesharing users. In contrast to station-based systems, dockless bikesharing users revealed that while having a higher education level, a higher income level no longer appears to be as significant as for station-based bikesharing use ([Chen et al., 2020](#); [Kaviti et al., 2019](#)). As for the adoption challenges, previous studies identified safety of riding, mandated helmet use, and the sign-up process could be barriers for station-based bikesharing ([Buck et al., 2013](#); [Fishman, 2016](#)), while pro-walking attitudes discourage the use of dockless bikesharing ([Chen et al., 2020](#)).

The experience of dockless bikesharing systems in user penetration and adoption have impacts and implications beyond bikesharing. Notably, this may have suggested a viable business model for the shared mobility companies. In fact, as the dockless bikesharing market appeared to hit a point of market saturation, new companies gradually turned to shared scooters as the new fuel for ridership and revenues. This new wave of scooter sharing and investments is changing and even challenging the common understanding of transportation in both positive and negative senses.

Scooter Sharing

Scooter sharing is the on-demand shared mobility service that provides access of scooters to users at a variety of locations ([SAE International, 2018](#)). As of August 2020, most available shared scooters around the world are lightweight electric standing scooters ([SAE International, 2019](#)). In many ways, a scooter sharing system is similar to a dockless bikesharing system. However, unlike the modern bikesharing systems that started as station-based systems, scooter sharing launched and remains predominantly dockless. This, coupled with other features of this new mobility option, creates an array of opportunities and challenges. In summary, the two main concerns about shared dockless bikes and scooters are improper parking, and risky or illegal riding behaviors such as riding on the sidewalk.

Concerning improper parking, the results of observational studies do not seem to agree with the public perception. For example, a survey on scooter sharing in Bloomington, Indiana reported that more than 73% respondents prefer designated parking areas for scooters, and close to 60% respondents call for banning scooters from sidewalks, both suggesting that there is a perceived issue with shared scooters occupying public space. Yet, the literature in this area suggest something different. Three observational studies across seven cities found that scooters that are improperly parked only accounts for 0.8%–6% of observations ([Brown et al., 2020](#); [Fang et al., 2018](#); [James et al., 2019](#)). These studies imply that improper parking may not be as serious as how it is perceived.

As for risky and illegal riding behaviors such as sidewalk riding, it appears that the lack of adequate and infrastructure facilitates the tension between shared scooter riders and other road users. For example, even in Denver, one of the more bicycle friendly cities in North America, 34% of the respondents of a survey indicated that while walking, a scooter hit or almost hit them, and 19% of the respondents stated a similar experience when driving ([Denver Department of Public Works, 2019](#)). In the same survey, 28% of the respondents indicated they would use shared scooters more if there were more dedicated infrastructure for riding. [Portland Bureau of Transportation \(2019\)](#) conducted both an observational study and a survey regarding use of scooter sharing in the city. They noted that scooter sharing riders would use bike lanes on low-speed streets, and incrementally higher percentages of sidewalk riding is observed on streets with higher speed limits. Meanwhile, the Portland study revealed that when a neighborhood low-traffic and low-speed street network is available, no users ride on the sidewalk, even without dedicated bicycle infrastructure. And, only 8% riders use the sidewalk with a protected bike lane available. People who are walking, biking, or riding a scooter are among the least protected road users, and many of the them are inexperienced as bicyclists. It is understandable that they choose the infrastructure type that they feel most comfortable with. Without a proper riding infrastructure such as a protected bike lane, sidewalks that are

designed for pedestrian become over-designed for scooter riders while roadways that are designed to move vehicles are under-designed for scooters. Sidewalk riding decreases the comfort level both for pedestrian and scooter riders, both of whom value their own safety first. It is the lack of infrastructure that force and intensify the interactions among different groups of road users, and influence how they perceive this shared mobility service.

Regarding the shared scooter rider demographics, they are similar to other shared modes (young, educated, higher income). There is observational evidence that scooter sharing attracts more women and racial minorities than other shared modes (Portland Bureau of Transportation, 2019; San Francisco Municipal Transportation Agency, 2019; Sanders et al., 2020). Despite the observational evidence that scooter sharing attracts a more diverse group of users, many non-riders perceive scooter sharing negatively. Besides, the broader demographic and increased number of riders can expose the less skilled population to a higher risk level. Indeed, some evidence points to scooter riders being unfamiliar with rules of the road and driver and rider expectations, calling for a need for more intuitive and low stress transportation networks to support novice riders. Relevant guidelines and changes should be developed and enforced to meet these emerging needs for transportation. However, an unprecedented pandemic in 2019 may point us in a new direction for shared mobility.

A Disruption to Disruptive Transportation

Shared mobility has increasingly disrupted conventional transportation systems. While critics might point to substituted low-impact modes (e.g., transit, non-motorized modes) as evidence of the negative aspects of shared mobility, many of the benefits revolve around providing a diversity of services that can provide the appropriate technology for specific trips and reduce reliance on space- and energy-inefficient modes (e.g., single occupant cars) for all trips. Travelers can consume appropriately scaled transportation services that meet their immediate needs, which is positive for constrained urban environments. This disruption has been enabled by technology, but also cultural shifts that result in attitudes and behaviors that foster increasing adoption of shared modes for many demographics.

The COVID-19 pandemic has upended all aspects of society, including shared mobility systems. Transit system ridership immediately plunged by more than 80% in most markets, following slow rebounds as economies opened (Transit, 2020). Shared mobility services have also been dramatically impacted (StreetLight, 2020; Thigpen, 2020) and it is uncertain how attitudes toward infection risk, job status, and rider demographics will affect rider behavior. People are riding bicycles and walking for transportation more often, there is some evidence that bikesharing and shared scooter riders have different behaviors compared to transit riders (Campbell and Brakewood, 2017; The Light Electric Vehicle Education & Research Initiative, 2020). However, at the time of this writing, there is a tremendous level of uncertainty related to the role of shared mobility in future transportation systems. Resilient transportation systems require service diversity. Shared mobility systems have increased diversity of transportation services more in the last decade than any other period in recent history. Shared mobility is essential for the continued economic viability of cities. As entire economies evolve to increase resilience against shocks, shared mobility will continue to adapt to assure continued mobility and access to urban destinations.

Introduction

We have known for decades that women have different transportation behavior, attitudes, and safety outcomes than men in both the developed and developing world. Analysts have continued to find major gender differences in travel and crash patterns even when controlling for important socio-economic factors that influence behavior such as age, household structure, life cycle, and employment status. These gender differences in travel behavior start early in people's lives and have endured long after travel behavior scholars predicted women and men's travel patterns would converge. They arise from a complicated web of remarkably persistent economic and educational factors, and, cultural, societal, and religious norms about women's role and rights to the city that substantially constrain their activities and choices even in the most industrial nations.

Indeed, some aspects of women's travel behavior have come to resemble men's as more women have obtained salaried employment outside the home as well as drivers' licenses and cars—and men have assumed more childcare and household duties. But converging trends in trip purpose and mode should not obscure the many gender differences which remain, differences which are far starker in the Global South, and act as serious constraints on women's ability to care for themselves and their families everywhere. These constraints are magnified by the failure of many societal institutions to respond to inherent physical differences in the safety and security needs of women and men—including vehicles that are not constructed to protect women in crashes or the constant sexual harassment that faces women in almost every mode of travel everywhere, but particularly the Global South. Nor should we ignore the fact that there are major but far less studied differences in travel patterns and needs between groups of women that often break along racial and ethnic lines. Finally, it is important to question why socio-demographic factors like income inequality and discrimination in labor and housing markets, factors associated with some differences between the sexes in travel behavior, so disproportionately impact women to begin with.

All transportation differences between women and men, and even between groups of women, are not indicative of deficiencies to be addressed or problems to be overcome of course. They can reflect personal attitudes and preferences. Yet these all these differences should be reflected in transportation policy and planning efforts to create transportation systems that respond appropriately to a variety of user needs and preferences, or "transportation markets." These differences assume even more importance when considering the need to support sustainable transportation choices when so many deficiencies in the transportation systems push women into increasing personal vehicle use. In addition many experts call for different approaches to transportation planning and modeling and project assessments by explicitly considering differential impacts on women and men.

The sections below address:

- gender travel differences that begin in childhood
- women's complicated travel patterns
- women's mode choices
- personal security
- women and new technology
- traffic safety
- conclusions and policy suggestions

Starting Early; Gender Differences in Children's Travel

More than four decades of research shows that parents often refuse to allow little girls to travel independently, or walk or cycle, without direct adult supervision, even as they allow comparable little boys to do so (McMillan et al. 2006; Yeung et al., 2018). Most studies show that girls are less likely to engage in active transport (walking and cycling) and more likely to be driven or accompanied to outside activities than comparable boys. Kepper et al. (2020) found that parents of female adolescents imposed more restrictions on their daughters' outdoor play in all types of neighborhoods. Colley and Buliung (2016) found that in Toronto girls were more likely to be driven to primary school than comparable boys and less likely to walk and that those patterns intensified over a 25-year period. Larouche et al. (2019) found that girls in New Brunswick (Canada) had lower odds of engaging in active transportation to school (cycling, walking) than comparable boys, especially in poor weather. Larsen et al. (2018) found that boys had higher odds of walking to school than girls in grades 5 and 6 in Toronto. A Welsh study found that girls were less likely to walk to secondary school than boys (Potoglou and Arslangulova, 2019). Some studies, however, did not find gender differences in some aspects of children's travel (e.g., Simons et al., 2018; Thigpen and Handy, 2018), but their methods and focus may explain these differential findings.

Parents' attitudes train girls to be more fearful of outdoor environments, discourage their independent travel, and accustom them to wait to be driven or accompanied as opposed to providing their own mobility (Rosenbloom and Plessis-Fraisard, 2011). It also puts a greater burden on parents, and usually the mother, to provide transportation for daughters. These patterns may well have life-long consequences as girls become parents; Aibar Solano et al. (2018) found, for example, that mothers were less likely to allow children to walk for a variety of purposes than were fathers in comparable households.

We have more limited information on children's travel in developing economies. A 2019 Iranian study found that girls who lived in a household with a car were less likely to walk to school for short trips than comparable boys (Hatamzadeh et al., 2017). The authors concluded that policymakers must address gender differences to increase rates of walking to school (in contrast to an earlier study in Tehran that did not find gender differences in active transportation to school Samimi and Ermagun, 2013).

Given the body of research that shows important gender differences among young children it is interesting to note that a significant share of studies of children's travel, particularly those focused on active school travel, do not separately analyze girls and boys' travel behavior nor their possibly differential response to various incentives designed to encourage active transportation to school (such as Safe Routes to School Programs).

Women's Complicated Travel Patterns

Women and men have had different travel patterns than one another for decades. Even in countries devoted to equality of the sexes, like the Nordic nations, comparable women and men have different attitudes and preferences about their family and childcare obligations which play out in their travel patterns. Early studies which found important gender differences in travel did not always control for salient variables; indeed some current studies still continue to compare all men to all women which obscures important socio-demographic factors like whether the women are employed outside the home and for how many hours per week, and the presence and age of children. Yet most recent studies are far more sophisticated, controlling for crucial variables—and they continue to show that women and men in industrial nations, even those in the paid labor force, have very different travel patterns because women are required to, or feel compelled to, spend more time on childcare and household responsibilities. The most common way salaried women respond is having generally shorter commutes than comparable men measured in distance and time, although those using slower modes sometimes incur longer commutes measured in time (Reuschke and Houston, 2020).

Women also have more complicated and variable trip-patterns than comparable men, in part because they accept a greater share of household and child- and eldercare responsibilities and alter their work trip commute in distance and time to accommodate those tasks. A 2019 study of travel-diary data from Australia, the UK, Spain, and Finland found that men and women often spend similar *total* time traveling, but that there were great disparities in trip purposes, mode choice, and how children's travel was arranged (Craig and van Tienoven, 2019). The researchers concluded that we continue to see a gendered distribution of labor and social parenting norms; with women the parent conducting child-serving travel no matter how egalitarian a society considered itself (i.e., Finland). A 2020 study found substantial differences in the travel patterns of comparable women and men but concluded that, rather than cultural roles or constraints, gendered labor market and employment structures created differences in commute distance by gender (Reuschke and Houston, 2020). The results are the same however.

Blumenberg et al. (2019) found that women in one car households in California often took that car—but rather than being a privilege it was an indication that the women had assumed the bulk of household and childcare duties. A recent German study found the same pattern; women in dual-earner families often took the sole car, accepting all childcare and household serving obligations, and had shorter commutes (Chidambaram and Scheiner, 2020). The German study also found that the gender imbalance was helped if and when the man took on additional household duties.

Han et al. (2020) found that dual earner households sometimes traded off activities requiring travel but that men tended to provide the routine trip of dropping kids off at school or childcare in the morning while women tended to take responsibility for the rest of the daily trips that arose. A Canadian study found that professional (employed) women spend more time than comparable men on home-serving tasks including shopping and taking care of children and other adults. These women also spent more time driving each day even if they worked the same number of hours per day as comparable men (Shirgaokar and Lanyi-Bennett, 2020). A Dutch study found that even when salaried women did not make a specific child- or household serving trip, they were responsible for

scheduling the trip for the other parent or adult in the household (Schwanen, 2007). These findings led both Craig and van Tienoven (2019) and Shirgaokar and Lanyi-Bennett (2020) to stress the need to understand gendered travel when adopting employment and transportation policies.

Gender gaps in travel are far greater in many countries in the Global South (Arman et al., 2018) generally linked to both less formal employment among women in turn linked to norms about what it is acceptable behavior for women (Cunha, 2006; Wafa et al., 2008). Women are forbidden or seriously constrained from using bicycles or electric scooters/three wheelers in many countries where the use of such a mode would substantially improve their mobility.

The most severe examples are in Muslim countries (Wafa et al., 2008). A Pakistani study found that women were substantially less likely to travel outside the home than comparable men, and were far more likely to walk when they did travel. The researchers concluded, as have those studying similar countries, that women's role was seen as a private one, with remaining in the home upholding family honor (Adeel et al., 2017). A later study by the same authors (Adeel and Yeh, 2018) found that 55% of women but only 6% of Pakistani men did not travel on any given day; women with *higher* levels of education and income who had children were the *least* mobile of all. The authors concluded this behavior was "triggered by a gender-based sociocultural environment which restricts female mobility due to family honor concerns."

Women's Mode Choice

The gap between women and men for some commonly used variables, such as having a driver's license, choosing to drive, and commute distance, has closed over time—but is still large enough to be significant. Colley and Buliung's (2016) study of 25 years of Toronto's "gendered transport" (1986–2011) finds that employed men drive more than comparable women and that the gender gap increases with the age of the traveler. The gender gap in driving has, however, decreased over the 25 years as more women entered the paid labor force, undertaken longer commutes, and head households. Women in 2011 were more likely to drive than in the past so other modes (public transit and walking) were not as intensely gendered in the Toronto region as they had been in 1986. Yet there was still a meaningful gap between women and men's modal choices and commute distances.

Research has consistently shown that women are more likely to use public transit and to walk for travel when they can than comparable men, although most studies show that as women become employed they are more likely to be auto drivers. Women have generally been far less likely to cycle than men in both industrial and developing nations (Sersli et al., 2020) although in countries with high cycling rates, like The Netherlands, there is a smaller gender gap. A 2016 study in the United Kingdom where cycling has been declining nationally for over 30 years, found that communities able to increase cycling overall saw no increase in the share of women cyclists and a decrease in the number of older cyclists (Aldred et al., 2020).

There is a large and still growing literature analyzing why women cycle substantially less than men particularly for transportation or commuting (as opposed to recreational cycling where women cycle slightly more often). In fact one scholar has argued that there is no further need for research on the topic; that we can and should formulate appropriate policies and programs to encourage women and men to cycle now based on the extant knowledge base. The literature shows that women tend to be worried about their safety and sometimes their security when cycling; they prefer grade separated cycling facilities rather than traveling with traffic (Aldred et al., 2017). A study in Brussels also found that women were substantially less likely to cycle than men due to concerns about traveling in lanes with motorized traffic and unpleasant auto fumes (de Geus et al., 2019). A US study of immigrants in San Francisco found that the lack of neighborhood safety was a significant deterrent to women cycling, an issue not of concern to most men (Barajas, 2020). There is some evidence that women also worry about their clothes, hair, and make-up when using cycling for their commute.

An important share of the literature on women and cycling focuses on the use of bike share programs, where bikes are available for rental at stations throughout a city generally by using a credit card. A Norwegian study found that a bike sharing program in Oslo was less accessible to, suited to, and used by women because they had significantly different travel patterns than the male cyclists for whom the system was defined (Bocker et al., 2020). The National Institute for Transportation and Communities (2019) found that disadvantaged women were suspicious of and concerned about bike share programs because some did not have credit cards. Others were worried that deposit charges would remain on their cards for some time reducing the amounts they could charge to those cards until the deposits were removed or they were afraid the bike might be damaged or lost after they returned it but the full costs would be charged to their cards.

The inability or unwillingness to cycle also reflects the societal roles that women assume or the constraints under which they operate (Prati, 2010). A 2019 Australian study found that women did not find cycling convenient for the myriad activities in which they had to engage (Bourke et al., 2019). Ravensbergen et al. (2020) argue that the planners must recognize the gender difference in cycling is not a biological or "natural" one but is simply a response to how society divides domestic and childcare responsibilities. The National Institute for Transportation and Communities (2019) found that disadvantaged women in three US cities reported multiple barriers to cycling, including the need to travel with multiple children and packages, the lack of space for a bicycle at their home or destination, and fear of assault or harassment when cycling. Women in many developing nations also fear assault or harassment and are kept from cycling for any purposes by cultural norms which view such behavior as inappropriate or even immoral (Iqbal et al., 2020). Ravensbergen et al. (2020) argue, however, that many of these issues are not intrinsic problems with cycling and could be addressed with better training and some changes to cycles (providing ways to carry packages or children for example).

Existing research has been limited by a failure to focus clearly on differences among groups of women (although there are exceptions). Many studies fail to control for *intersectionality*, racial and ethnic differences in travel patterns and attitudes that may persist even when controlling for income, employment status, and household characteristics. Women of color often face substantial discrimination in the labor market which substantially impacts when and where they work, which in turn impacts the transportation modes available to them or which they can afford. In the Global South women in general, but particularly women of color, are often unable to use regular buses, BRT, or rapid rail systems because they cannot afford more formal modes and/or those modes do not serve the far-flung location of their jobs, which often differ significantly from the jobs available to men. In industrial nations women of color are often forced to make long difficult public transit trips, traveling further for work than other women (or men) with the same income (Salon and Gulyani, 2010).

Personal Security

A significant barrier to women's travel is fear of crime, sexual harassment, and physical assault; women around the world make major changes in all aspects of travel in response to these fears (Adur and Jha, 2018; Chowdhury and van Wee, 2020; Gardner, et al., 2017). Brazilian researchers found that far fewer female Brazilian university students felt safe traveling to campus than male students; these women, often forced to walk lacking other alternatives, would often take longer circuitous routes where they felt they were less likely to be crime victims (Capasso da Silva and da Silva, 2000). More than 60% of female riders of the BRT system in Barranquilla, Columbia reported being victims of sexual harassment while using the system; overcrowded buses had the most negative impact on their sense of security but they were also concerned about traveling at night or alone and inadequate lighting (Orozco-Fontalvo et al., 2019). Kash (2019) found that 37% of women using public transit in Bogota and Soacha, Columbia reported substantial sexual harassment; they responded by adopting what she calls "defensive postures," avoiding travel at certain times, traveling in groups, seeking a defensible position in a transit vehicle, taking more expensive modes, and even abandoning a trip entirely.

Researchers in New Zealand found that many female public transit riders, particularly women of color, were fearful of being a victim and were extremely sensitive to transfer and wait times at public transport terminals because they felt especially vulnerable at such points. They carried open cell phones, constantly checked apps on vehicle arrival times, and wore headphones to avoid hearing verbal harassment (Chowdhury and van Wee, 2020).

The problems of sexual harassment in the Indian sub-continent are particularly well known and have traditionally been ignored by local authorities (Mitra-Sarkar and Partheeban, 2011; Malik et al., 2020). Gadekar (2016) found that women in the Indian sub-continent are conditioned from childhood to accept a negative image of themselves and to understand their limited rights to the city from the daily harassment commonly known as "eve-teasing." Women are forced to endure cat calling, lewd remarks, fondling, and rubbing by men as they pass on the street, wait at bus or train stops, or ride aboard vehicles (In 2012, in an incident that made international news and sparked domestic outrage, a group of males (including one boy) gang raped a female college student on a bus in Delhi; she was later flown to Singapore for medical assistance but died of her injuries. The men defending themselves by saying no decent women would have been traveling alone without a male member of her family (she was traveling with a male friend whom the group beat) (Phillips et al., 2015). The boy received three years confinement, one man committed suicide while in jail, and the remaining men were hanged in 2020 for the crime. There were mass protests by women around the country and the Indian government undertook a study of the conditions that led to the attack; they made some changes—additional lighting, enhanced patrols of public transit stops (although the incident occurred on a vehicle) and creating apps to report attacks—but critics charge that the government did little to address the basic cultural problems). Kuruvilla and Suhara (2014) found that their entire sample of 120 women university students in Kerala had been subjected to almost daily sexual harassment, entirely on public transit vehicles. A study in Labore (India) found that harassment at Bus Rapid Transit (BRT) stations and in buses was a major challenge to women travelers (Malik et al., 2020). A study in New Delhi found that women's perception of the likelihood of being sexually harassed on public transit was consistent with self-reported occurrences but they underestimated the likelihood of attacks on informal transport modes (like taxis and auto-rickshaws). They researchers also found that women viewed incidents of sexual harassment as much more serious than did men did (Madan and Nalla, 2016).

Women in India and Pakistan respond by travelling only in groups or with male family members or colleagues; they change the times at which they travel or their destinations, they avoid certain places (like public transit transfer points) and they carry their cell phones open in their hands at all times. Not surprisingly a number of women in developing nations use more expensive options when available (taxis) or report planning to buy automobiles to avoid the worst of these incidents (Malik et al., 2020; Natarajan, 2016) in spite of UN and international focus on promoting safe, affordable, accessible, and sustainable public transport. Hsu (2009) found in fact that women in both California and Taiwan who were fearful about harassment using public transit thought buying a car was the only reliable solution to the problem. Gekoski et al. (2015) noted that the same phenomenon among women who had the resources to purchase a car but concluded that women in countries with a wide income disparities often do not have access to cars and are likely transit captives.

Sexual harassment is largely ignored by transportation planners, public transit agencies, and police for a variety of reasons. Kash (2019) found that transit officials in Bogota often believed that victims were lying or mistaken, sexual harassment did not really hurt victims, victims were often at fault, it was "natural" for men to behave in these ways so their behavior could not be changed, and finally that transit officials could not be responsible for societal norms and values (the last not an uncommon response in multiple transit systems). The lack of appropriate official responses creates a vicious cycle in both the developed and developing world:

women do not know that they can report such actions or they realize the futility of doing so while transportation authorities use the lack of reports of harassment or assault as proof that there is no problem (Natarajan, 2016). The majority of these incidents are not viewed as crimes; even if they are, the perpetrators are generally gone before law enforcement can be summoned so police often do not bother to respond. Bystanders have no idea what to do or when. There are often jurisdictional issues as well even when harassment serious enough to be considered a crime occurs—do transit police or the police of a local jurisdiction respond when it occurred on a train or bus or at a transit stop?

Some transit operators in Bangladesh, Brazil, Dubai, India, Japan, Mexico, and Nepal provide women-only coaches on trains but this practice can divide families or colleagues traveling together. A British study noted that women-only coaches, although an effective way to reduce unwanted sexual behavior, were “. . . essentially a ‘short-term’ fix and reinforce a message that women must be contained and segregated in order to protect them” and as such they did not recommend this option for countries like Britain where they “. . . would be a retrograde step.” (Gekoski et al., 2015, Recommendations, unpaginated). Moreover, studies show that gangs of men often wait at the doors of such coaches to harass and attack women as they exit (although Graglia (2015) argues that women-only coaches in Mexico City were the basis of an important rights-based movement).

Loukaitou-Sideris (2009) surveyed a number of US public transit operators and found that very few had programs or policies that targeted the safety and security needs of women riders—even though most felt that women had distinct needs. In fact only a third believed that it was the responsibility of transit systems to address these issues because they were a larger societal problem (echoing the sentiments that Kash found among South American transit officials). Since that time a few large public transit operators in North America have developed policies or programs to make women (and men) who are victimized aware that these behaviors are either forbidden by the operator or illegal and to make reporting harassment easier. Some transit operators provide guidance to by-standers as well the victims themselves on what to do at the time of the attack and how to report; some have created special phone apps allowing victims and witnesses to report such incidents immediately. These efforts are often accompanied but advertising and education campaigns stressing that such behavior is unacceptable and can be reported/ But we have little information on the impact or effectiveness of such programs.

A 2015 study undertaken for the British Transport Police and the UK Department for Transport (Gekoski et al., 2015) found that transit operators in industrial countries had considered or (infrequently) adopted a variety of initiatives to address sexual harassment and violence. In addition to providing women-only coaches, these initiatives included better station and vehicle maintenance, emergency alarms or panic buttons or phones on vehicles or platforms, dedicated places at transit hubs to report harassment and assault, hotlines to report incidents, request stops on buses, real-time scheduling information and apps, and legislative changes providing harsher punishments for offenders. The study also found that many transit agencies improved surveillance in several ways: *formally* by dispatching high visibility staff and police as well as undercover operatives; *technologically* by deploying CCTV cameras on vehicles and at transport hubs, and *naturally* through better lighting and visibility throughout the network. They also developed community outreach programs and awareness campaigns to make it clear that this behavior was unacceptable and could and should be reported. The study found however, that there were numerous examples of national and international initiatives in this area, “Unfortunately there are few rigorous evaluations using before and after measures of crime/incidents or randomized control trials to provide evidence of whether such initiatives achieve their aims” (Gekoski, Executive Summary, unpaginated.)

Overall, sexual harassment and even physical attacks continue to be underreported, under-policed, and underestimated crimes and practices that make women’s travel difficult and even dangerous around the world. Few systems are undertaking major efforts to address these issues in either the Global South or the industrial world. The limited responses of so many transportation authorities, including their failure to even acknowledge let alone keep track of such incidents, impose serious burdens on women, the victims, without addressing the perpetrators at all.

Women and Acceptance of New Transportation Technology

Women have long been known to have different attitudes and preferences toward certain modes and travel choices; women are for example more concerned about the environment and making personal choices that support sustainability. It surprised some researchers then to find that women were suspicious of or viewed pooled transportation services, like Lyft and Uber, and automated vehicles, negatively. A study in the Czech Republic, for example, found that women were less likely to be positive toward connected and automated vehicles than comparable men (Havlickova et al., 2020). A Finnish study found that women held less positive feelings toward automated vehicles (Liljamo et al., 2018); Hohenberger et al. (2016) also found that German women were more likely to have negative emotions about automated cars and were unwilling to say they would use them. The gender differences were not explained by age or education effects. These authors suggested stressing ways to reduce women’s anxiety about such options and promoting the aspects that women did or might have pleasurable about automated vehicles.

All indications are that women’s responses to both current pooled options and potential shared (or individual) automated vehicles are a combination of security and safety concerns and lifestyle issues. Women are worried about cars that drive themselves and lack confidence in the power of technology to deal with all roadway problems. They are also anxious about boarding vehicles with strangers, particularly men, already aboard, especially if they have to share bench seating. Finally women’s attitudes are also conditioned by the childcare and domestic responsibilities they face. Women may prioritize time over money; they may simply not have the time for the route detours needed for other travelers. Moreover, they are often traveling with children or older relatives as well as carrying strollers and car seats and packages. And they may need to make multiple stops on any journey (Institute of

[Transportation Studies, 2019](#)). Women may find it hard to see how pooled resources now or in the future will fulfill many of their needs or address their personal safety and security concerns.

Traffic Safety

The Industrial World

Women drivers and pedestrians are generally far safer than comparable men in the industrial world; women have substantially fewer auto and pedestrian crashes than men although they are more likely to be seriously injured or die in crashes of comparable severity ([Rosenbloom and Herbel, 2009](#)). In 2017, women in the European Union accounted for less than a fourth of total traffic fatalities (as a pedestrian, driver, or passenger) and a third of the number of male traffic fatalities ([European Commission, Table 1, undated](#)). In 2017, women's traffic fatality rates were 24.0 per one million population in the EU28, a ratio that was unchanged since 2006 (EC, Table 2, undated). Women in fatal traffic crashes in the EU were substantially less likely to be driving a vehicle when killed in it. In fact in 2017, there were only three EU countries where driver fatalities accounted for 50% or more of all women's traffic deaths (the Netherlands, Austria, and Denmark) and more than a dozen EU countries where female driver fatalities constituted less than 20% of all women's traffic deaths. Women in the EU in fatal traffic crashes were largely dying as pedestrians or passengers in vehicles in spite of being involved in a lower absolute number of such crashes. Men in contrast were substantially more likely to die as the driver in a traffic fatality; there was no country in the EU 28 in which driver fatalities were less than half of annual male traffic fatalities. In the majority of EU countries in 2017 almost three-quarters (and sometimes more) of all male traffic fatalities were driver fatalities (EC, Figs. 8a and 8b, undated).

Traffic fatality rates say little about who is to blame but the EU did find that women drivers were less likely to be cited by the police for serious or fatal traffic crashes in five European countries between 2005 and 2008, although citation rates are not necessarily an accurate evaluation of crash responsibility (in part because one cause is often attributed to a crash due in reality to sequentially linked contributing factors). When cited as drivers by the police for auto crashes in which they were involved, women were less likely to be driving in the wrong direction or traveling at excess speeds but more likely to be stopping short or taking action prematurely than men (EC, Fig. 9, undated). These data, moreover, did not include information on the blood alcohol level of the drivers, although we know that alcohol is involved in large number of crashes and that men are more likely to have been drinking than women.

Good data by sex on driving or incurring a pedestrian crash while impaired are limited for the European Union. A 2012 report by the World Health Organization (WHO) found that 17% of all women's pedestrian crashes in Europe involved alcohol compared to 40% of men's pedestrian injury crashes. Among men 15–29, 46% of road injury crashes involved alcohol; the comparable figure for women that age was 18%. Among those 30–44 years of age, 25% of the road crashes of men that involved an injury were related to alcohol; the comparable figure for women was 25%. Alcohol was involved far more in injury related crashes in all modes in the Baltic countries and Central Europe for both sexes; in a few of those countries women's injury crash rates involving alcohol consumption equaled or exceeded men's ([WHO, 2012](#), p. 50).

US data show similar patterns, in spite of the fact that women drivers have outnumbered male drivers on US highways for a number of years. US women are safer drivers and die more often as passengers than drivers and as pedestrians more than passengers. In 2018 roughly 86% of both men and women 14 years of age and older were licensed drivers in the US—but that total included 2.5 million more female than male drivers (FHWA, Table DL20b, 2019). [US National Highway Safety Transportation Administration \(NHTSA\)](#) data show that in 2018 men constituted over three-quarters of drivers involved in a vehicle crash in which one or more occupants died. But women made up half of the occupants who actually died and almost two thirds of occupants injured in those vehicle crashes. Female drivers, however, were involved in a higher percent of the total number of crashes that involved injury (but not death) to one or more vehicle occupants than men but in fewer of the total number of crashes that involved only property damage. Yet in both cases women's crash involvement rate per 100,000 female drivers (not population) was lower, sometimes substantially, than men's (NHTSA, Table 57, undated).

Data from the [US Insurance Institute for Highway Safety](#) show that passenger death rates have fallen significantly in the 20-year period from 1998 to 2018, but faster for men than for women. The number of women who died as a passenger in a personal vehicle dropped almost 40% over that period but declined almost 46% for men. In 1998, women constituted 49.7% of all passenger fatalities but that rose slightly to 51.7% in 2018. In 1998, women were 29.8% of all pedestrian fatalities rising slightly to 30.3% in 2018. The more sobering statistic is that while the total number of driver and occupant deaths in traffic crashes declined substantially over the 20-year period, the number of pedestrian deaths increased 29% for women and 26% for men (IIHS, calculated from table, "Motor Vehicle Crash Deaths by type and gender, 1975–2018."). It's also important to recognize that pedestrian injuries and even deaths are officially underreported around the globe; researchers using hospital ER and admitting data find that the actual number of serious pedestrian crashes may be from three to four times higher than crashes reported by the police/official crash data—especially among the young and old. A British study that corrected for that problem found that women and older people were far more likely to be injured in a pedestrian fall than other travelers in ways not fully recognized by official data ([Aldred, 2018](#)).

The role of alcohol and other impairments also breaks along gender lines. US women drivers were also far less likely than men to be involved in fatal vehicle crashes (where anyone died) in which they were alcohol impaired. In 2018 women accounted for 26.4% of all alcohol-impaired drivers involved in a fatal crash and just under 20% of all those drivers with a blood alcohol level at or over 0.08 g/dl (the common dividing line for driving under the influence in most US states). This was a 1% increase in the number (not share) of female drivers with a blood level 0.08+ g/dl involved in a fatal crash over the 10-year period 2009–18 (NHTSA, Table 3,

2019)—in spite of the fact that the total number of drivers (of both sexes) involved in such crashes increased 12% and the number of women drivers on the road went up 8.4% over the same time period (computed from NTSA, Table DL20, 2010 and 2019). We would, of course, hope for alcohol related fatal and other crashes to decrease sharply due to better education and enforcement (as have total driver and occupant crashes), but women drivers continue to be a much smaller share of the impaired driving problem than male drivers.

The gender differences in crashes and crash outcomes are a result of a combination of factors. Women drivers have fewer fatal crashes because they drive less, do so more safely, and are less likely to be impaired (by illegal drugs or cannabis as well as alcohol) (Lloyd et al., 2020). Women are also more likely to follow the rules, wear their seat belts, and not speed (Rosenbloom and Herbel, 2009). A recent study of how drivers use GPS devices in their vehicles, for example, found that men were more likely to violate the speed limit and more frequently than women (Yared et al., 2020). At the same time, the data above show that women are more likely to die (or be seriously injured) in the crashes in which they are involved whether as a pedestrian, driver, or passenger.

Women's poorer vehicle crash outcomes are due to several factors. First, the protection systems in cars are designed largely for men and not for women (or for pregnant women). In fact, it is practically impossible for women, who are generally of shorter stature than the average man, to be sitting in the safest places in a car. Second, women are on average frailer and thus more likely to die in pedestrian crashes (World Health Organization, 2002). Vehicle concerns are not being well addressed because regulators have not required manufacturers to specifically do so; a recent EU study concluded that most safety assessments and vehicle tests use the average size male as the regulatory model, excluding average sized women (Linder and Svedberg, 2019). Thus we have not substantially increased our knowledge of how to make personal vehicles safer in a crash for women occupants (driver or passenger). We also lack good information on where and how a pregnant women should wear a seat belt although a recent study found that belted/restrained pregnant women suffered less severe injuries than unbelted women (Schellenberg, et al., 2020). We still do not know, however the impact of seat belts in a crash on the fetus; one study found that fetuses sometimes died in fairly minor crashes in which the mothers were not seriously injured.

There are also some indications that younger women may be closing the gender gap in crash rates (IIHS, undated). Yet some of these crashes may result from the societally imposed roles that many women assume; women who are driving with children are particularly prone to having their attention diverted from the driving task (Maasalo et al., 2016, 2017). Kelley-Baker and Romano (2014) find that the percent of women drinking and driving with children in the car has also steadily increased and at faster rates than among men (although the growth rates reflect the very low starting point for women). Yet most drinking drivers are still men and having a child in the car seems to induce both sexes to drive more safely overall (Maasalo et al., 2017).

Developing Nations

We lack good gender data on traffic crashes and outcomes in most developing nations—a significant problem in itself. The World Health Organization reported in 2002 that there was a steadily rising number of road traffic crashes in developing nations as a result of the substantial increase in motor vehicles and vehicle congestion. A 2020 study found that 93% of all global road traffic injuries take place in low- and middle-income countries; worldwide, traffic injuries are the eighth leading cause of deaths in these countries, costing an estimated 3%–5% of Gross Domestic Product, in addition to the major financial impact on families (Lomia et al., 2020). Georgia, a middle-income country in the Caucasus region of Eurasia, has one of the highest road traffic injury rates of any country in the European region—such crashes were the second leading cause of death among women 15–49 years old and the principal cause of death for women 15–35 in both 2006 and 2012 with no improvement over time.

Lomia et al. (2020) analyzed the traffic crashes of 843 Georgian women 15–49, 78 of whom (or 9.3%) had died in the crash; they did not conduct a comparative analysis with male crash victims. The researchers found that 71.8% of the fatal crashes occurred when women were the passenger in a personal vehicle; only 5.1% of women who died were driving the vehicle in which they were riding. Twenty percent of women who died were pedestrians; all other modes accounted for the remaining 3%. Most of the women who died did so at the scene of the crash (and not on the way to the hospital or at the hospital). Surprisingly the victims were equally divided across the income spectrum; 60% were married and 60% were aged 40–49. In fact, the researchers found that being employed, married, and having completed a secondary education was associated with a greater likelihood of dying in a traffic crash, a finding they could not fully explain. It is possible that such women just had greater total traffic exposure although the authors postulated that more highly educated and employed women not only had greater access to automobiles but were more likely to flaunt basic traffic laws because of their time-compressed schedules.

Men significantly outnumber women as road injury victims in developing nations however—by roughly double—largely but not entirely because women rarely use automobiles so men have higher exposure to the risk of vehicle related traffic injuries. Men in developing nations are also more likely to suffer traffic fatalities because of extremely risky behavior; a study in Karachi found that men were substantially more likely to jump on or off a moving bus amidst very heavy traffic. Pedestrian deaths are a leading cause of traffic deaths in developing nations, particularly among men, because of the large number of two- and three-wheeled motorized vehicles that mix with pedestrian traffic, the failure of all vehicle drivers to observe traffic laws designed to protect pedestrians, and poor or non-existent pedestrian facilities that force travelers into the roadway.

WHO (2002) noted that women are more likely significantly impacted by traffic crashes than men because they have limited access to medical facilities and medical insurance and lack money to pay for childcare or other domestic duties when they are too injured to perform these tasks. Moreover, when the male member of a household dies or is seriously injured in developing nations, the whole family may suffer financial devastation.

Conclusions and Policy Implications

Women and men's travel differs, differences that begin in early childhood and persist as learned behaviors. Most research shows that women and men's travel patterns still differ even as other factors (employment, commute distance, licensing and auto use, etc.) have narrowed the travel gap between men and women. Women are more likely to undertake commute trips than in the past since roughly two-thirds of all women in the industrial nations have salaried employment outside the home, more than 60% (and almost 90% in some countries) have drivers licenses, and many own or have primary access to a car. Women's travel patterns, however, still reflect an unequal distribution of household and childcare and eldercare obligations, all of which play out in their travel patterns. Women in most industrial nations make more trips, although they generally travel fewer miles, than comparable men; they have more complicated travel patterns because they often link multiple trips together far more than do men while providing transportation for children and older relatives traveling to places they themselves do not need to be.

Women in developing nations are often limited by cultural and religious norms to the kinds of out-of-home activities in which they can engage and the kinds of transportation options that are considered suitable for their use. Women, for example, are often sanctioned if they try to cycle or drive three-wheeled vehicles or motorized scooters, although those options are generally the only ones they could afford and would substantially increase their employment and educational opportunities and decrease their total travel time. In a number of predominantly but not exclusively Muslim, countries women are forbidden to work or even travel outside the home; in other countries when they do they are harassed as they walk or use public transit. In almost every country in the world far fewer women cycle than men, although this is a cheap and sustainable mode that could enhance their health and mobility.

It is inescapable that women are also far more likely to be victims of sexual harassment and violence as they travel in both the developed and developing world; public officials and transit agencies have done little to address these issues which pose substantial barriers to women's travel, creating anxiety and fear even among women traveling in industrial nations. Women are generally safer drivers than men at all ages but they are substantially more likely to die as passengers in a private vehicle than as a driver; moreover they are more likely to die in vehicle and pedestrian crashes of comparable severity because they are more fragile on average and public policies have not required automobile manufacturers to understand women's vehicle protection needs or to alter vehicle design to make those vehicles safer—even for pregnant women.

What we know now about women's travel patterns and needs also reveals the many things we do not know or on which we have not previously focused. Many researchers call for greater attention to intersectionality, understanding how gender interacts with race and ethnicity and class and immigration status to create important travel differences among various groups of women. Others note that members of the LGBTQ+ community often face similar safety and security issues but they or their needs are not included in these discussions. We also need to better understand the implications of all these gender differences for women's ability or willingness to use new technology, in an age with rapid changes in modes of service, communications, and dependence on the so-called gig or part time economy facilitated by online platforms. It is also important to question why socio-demographic factors like income inequality and discrimination in labor and housing markets, factors associated with some differences between the sexes in travel behavior, so disproportionately impact women to begin with.

The failure to recognize persistent differences in the travel patterns and needs of women and men, and among individual groups of women, play out in public policy decisions and project evaluations. Not all differences between women and men require remediation of course or raise equity concerns; they must be reflected in our planning efforts however in order to ensure that transportation plans and system decisions reflect and respond to the various transportation "markets" that exist in increasingly diverse communities. Substantial evidence suggests, for example, that women are not well served by massive rail projects or Bus Rapid Transit projects which many low- and middle-income nations are constructing (often with major funding from international development banks) because they do not well serve the spread-out employment and other destinations to which women travel and often make no provisions to ensure women's personal security. Worse governments often discontinue or underfund local buses, and try to stamp out informal transport services (taxis, jeepneys, etc.) on which many women in developing nations rely, when major guideway projects are built, locking women out of employment options and subsistence jobs in which they formally engaged. It is important to attempt to understand how different plans and projects will and impact women and men differentially and provide appropriate options for different users. [Adom-Asamoah et al. \(2020\)](#) for example, examined rural transport infrastructure projects in Ghana and found that they impacted women and men differently because their travel patterns were so different. Adom-Asamoah et al. concluded, "... the issue of gender must be re-negotiated and properly understood."

Many analysts feel we know enough about how to encourage more women to cycle either for transportation or recreation (or both) to enact proper policies and programs—yet most governments at all levels fail to do so. Few governments expend resources for pedestrian facilities and bus stops, even though the lack of such facilities or their poor state of repair pose serious safety problems to many women. Certainly these problems are worse in the Global South where women frequently walk as their only travel mode or to connect with public transit, often with children born and unborn and packages, etc. Yet the lack of adequate pedestrian and public transit infrastructure (safe and accessible bus stops, for example) plagues many industrial nations in whole sections of urban areas creating disproportionate problems for older women or those traveling with children, or wheeling baby carriages or strollers, or carrying packages, etc. and clearly inhibiting active travel and public transit use. Overall many travel behavior researchers, government officials, and policy analysts still fail to consider the persistent differences in how women and men evaluate, perceive, and use (or not) different modes, and their significant differences in travel patterns and purposes. Public policies as a result often fail to meet women's needs or make various travel modes more practical, safer, secure, and convenient for women and men travelers.

Biography

Dr Sandi Rosenbloom is a Professor of Community and Regional Planning at the University of Texas at Austin. She has long studied the travel patterns of women, older people, and those with disabilities. She helped organize the first international conference on women's travel issues in 1978 and has been a member of the Conference Steering Committee for the subsequent five international conferences (the sixth held at the National Academies of Science, Engineering, and Medicine Beckman Center in Irvine, California in September, 2019).

Introduction

Driver stress, as defined by the transactional model (Matthews, 2001b, 2002), is an outcome of the interaction of the person and the traffic situation and emphasizes that stress is an unfolding process in the dynamic interchange with other road users and situational encounters. According to the model, environmental stressors are appraised and may elicit maladaptive cognitions and stress responses that tax the person's ability to cope. These cognitive stress processes support two forms of outcome: subjective responses such as anxiety, anger and tiredness, and performance outcomes such as impairment of psychomotor control and changes in speed. The impact of these stressors is moderated by personality factors and further influence how external stimuli are appraised. The ongoing selection of coping strategies may be effective or ineffective for driver safety. For example, a driver who is vulnerable to frustration whilst driving and copes by becoming confrontational can be expected to exhibit a discernible pattern of conflict laden encounters leading to greater risk taking.

This chapter reviews key findings of the development and validity of these measures of driver stress and performance outcomes. The application of the instruments for assessing individual driver stress vulnerabilities for targeted delivery of fleet safety interventions are also discussed.

The Driver Behavior Inventory (DBI)

Work began in the 1980s at Aston University in the UK with a series of studies to design an instrument to measure dimensions of driver stress (Gulian et al., 1989, 1990) that hitherto had not been attempted in such a comprehensive way. Initial studies tested hypotheses based on the transactional theory of stress (Lazarus and Folkman, 1984). The Aston studies proposed that driver stress is a compound function of factors both intrinsic (traffic conditions) and extrinsic (personal life) to driving. Gulian et al. (1988) described the development of the driver behavior inventory (DBI) using a few items from Parry (1968) and Stokols et al. (1978) with the remainder emerging from interviews with drivers and their driving diaries. Analysis of the pilot questionnaire highlighted a cluster of traffic situations, as well as feelings about driving and other road users, which were associated with and predictive of driver stress. In a follow-up study using a modified DBI (Gulian et al., 1989), factor analysis of responses to 31 items using a fresh sample revealed a 5-factor solution. Scales derived from the factors showed reasonably high internal consistency and accounted for about 40% of the variance as well as a 'general driver stress scale' from a one-factor solution:

- Driving aggression (AGG)
- Dislike of driving (DIS)
- Heightened alertness when driving (AL)
- Irritation when overtaken (IO)
- Tension when overtaking (OT)
- General driver stress' factor (GEN) constituted about 18% of variance.

The DBI scales have been investigated in relation to demographic characteristics and driving history and the extent to which these stress vulnerabilities correlate with self-report measures of personality, mood, stress, and performance. Studies have fairly reliably shown that the DBI factors are not general personality factors, but relate to various behaviors and reactions while driving (Dorn and Matthews, 1992; Glendon et al., 1993). The DBI traits are only moderately correlated with standard personality measures such as neuroticism (Matthews et al., 1997) and have greater predictive validity for driving-related criteria than do standard personality measures (Dorn and Matthews, 1995).

The Driver Stress Inventory

The Aston team then undertook a series of validation and reliability studies and developed the transactional model further (Matthews et al., 1996, 1997, 1998; Matthews, 2002). From these studies, the DBI was refined and extended given that the overtaking factors was found not to be stable and loaded predominantly on to AGG. Assessing thrill-seeking and fatigue reactions to driving were also deemed important components of stress but were not included in the original DBI.

The newly formulated DSI measures five distinct dimensions of stress vulnerability (Matthews et al., 1997):

- Driving aggression (AGG): characterized by negative appraisals of other drivers that tend to generate feelings of anger and dangerous driving behaviors.
- Dislike of driving (DIS): associated with negative self-appraisal and generates negative mood states and worries which tend to interfere with task performance.
- Hazard monitoring (HM): reflects the active monitoring for hazards to preempt threat by the vigilant search for danger.
- Thrill-seeking (TS): defined by enjoyment of danger and increased risk taking.
- Fatigue proneness (FP): associated with errors and lapses and predictive of loss of task engagement reflected in a lack of willingness to engage in effortful, task-focused coping.

The DSI is therefore a more comprehensive measure of affective reactions to driving. The alphas coefficients for the scales were found to be higher than those for DBI scales (Matthews et al., 1997). However, the homogeneity of the DBI and DSI scales have repeatedly been found to be satisfactory (Hoare, 2001; Glendon et al., 1993; Gulian et al., 1989; Lajunen and Summala, 1995; Matthews et al., 1996). It can therefore be concluded that this measure of driver stress is psychometrically sound. However, Westerman and Haigney (2000) identified somewhat different factor solutions although the three largest factors were recovered: AGG, AL and DIS as found in later studies (Kontogiannis, 2006; Taubman-Ben-Ari, 2008). The DBI/DSI dimensions have mainly been tested on English and American (US/Canadian) car drivers but also seems to generalize across to different cultures (Finnish: Lajunen and Summala 1995; Japanese: Matthews et al., 1999a; Greek: Kontogiannis 2006; Chinese: Qu et al., 2016) and different professional driver groups (truck drivers: Bergomi et al., 2017; Hartley and Hassani, 1994; police drivers: Gandolfi and Dorn, 2003; bus drivers: Besharati and Kashani, 2017; Dorn et al., 2010).

Driver stress may directly affect the driver's choice of behavioral coping strategies so a separate measure of coping with driver stress called the Driving Coping Questionnaire (DCQ: Matthews et al., 1997) was also developed based on previous work (Matthews et al., 1993). The DCQ aimed to capture how people tend to cope with the stress of driving and includes the following dimensions:

- Confrontive coping (CONF): standing up to others to assert one's needs or relieving one's feelings through risk-taking e.g. tailgating a slow vehicle to encourage them to move out of the way.
- Task-focus (TF): making an effort to drive safely when demands are high e.g. slowing down and being more vigilant.
- Emotion-focus (EF): regulating feelings and thoughts about events, criticizing oneself for mistakes, e.g. thinking reassuring thoughts when upset, or reflecting on why another driver committed an unsafe action.
- Reappraisal (RE): looking on the bright side when driving is demanding e.g. viewing the drive as a learning experience.
- Avoidance (AV): physical or mental disengagement from events by suppressing negative feelings. For example, a driver might avoid a particularly congested route or seek to remain detached when driving is demanding.

A consistent relationship between the DBI and DCQ scales have been established (Hoare, 2001; Matthews et al., 1997) suggesting that coping mediates the associations between driver stress vulnerability and stress outcomes. For example, several studies show that CONF is positively associated with AGG and TS. EF is positively related to DIS with drivers high on DIS being more prone to negative emotional coping that diverts attention from the driving task toward self-blame and worry. On the other hand, TF is positively correlated with AL/HM suggesting that drivers who focus on the problem appear to direct their efforts toward the task itself by adopting rational strategies such as information seeking, taking precautions, and making plans. FP is linked to emotion-oriented driving and reducing discomfort.

Stress Vulnerabilities and Performance Effects

Tables 1 and 2 show that the validity of the DBI/DSI scales has been tested using three main methods showing converging evidence; self-report, driving simulator, and field studies with self-report methods being most commonly used. The self-report studies have generally found that the DBI/DSI scales correlate with existing validated instruments and linked with demographic characteristics

Table 1 Driver behavior inventory (DBI) review

Reference	Method	Scale	Participants	Results	Comments
Brewer (2000)	Self-report study	DBI	249 Australian bus drivers and non-bus drivers (94% male). Age ranged from 19 to 64	AGG was predicted by AL, OT, and IO	Correlations between the DBI and other questionnaires (e. g., Driving Anger Scale) not reported
Chen (2007)	Self-report study	DBI	194 Taiwanese driver participants; mean age = 41.6. At least one years' driving experience	High AGG drivers reported higher frequency of mobile phone use	AGG validated with risk taking behavior
Dorn and Matthews (1992)	Self-report study	DBI	Study 1: 60 British participants (55% male); mean age = 28.8. Study 2: 54 participants (51% male); mean age = 28.9	In study 1, neuroticism is associated with ineffective coping strategies and extraversion is associated with use of rational, problem solving strategies. In study 2, DIS was associated with high neuroticism and low affection	DBI traits only moderately correlated with standard personality measures and have greater predictive validity for driving-related criteria
Dorn and Matthews (1995)	Driving simulator study	DBI	Study 1: 73 British participants; mean age = 44.3. Study 2: 93 participants; mean age = 22.7 Samples combined = 166	One sample performed a passive' drive, and the second sample performed an "active" driving task. The DBI traits were more strongly related to mood than personality traits. In both studies, DIS correlated with greater post-task tension and depression. DIS was the strongest single predictor of post-drive mood. Prior to the drive, participants also rated accident risk, driving skill, and judgment, for themselves and for peers. DIS rated themselves worse than peers and DIS was the strongest single predictor of self-ratings	The DBI predicts emotional stress in simulated driving
Glendon et al. (1993)	Self-report study	DBI	61 British drivers (67% male); mean age = 41.4	Drivers completed the DBI on two occasions separated 5-month interval. Coefficients alpha, test-retest reliability, and correlational analyses between the five scales revealed reliable scales. GEN was found to be particularly robust. AL was less robust and minor changes improved their reliability	
Gulian et al. (1989)	Self-report study	DBI	112 British participants (27% male); mean age = 44.00; mean driving experience = 20.0 years	Factor analysis revealed a 5-factor solution with reasonably high internal consistency as well as a "general driving stress scale" from a one-factor solution. Cognitive Failure Questionnaire (CFQ) scores correlated with AGG, DIS, and GEN	The original DBI research paper
Gulian et al. (1990)	Self-report and diary study	DBI	152 British (59% male) mainly commuter participants; mean driving experience = 22.0 years	13 GEN items correlated with Daily Driving Stress (DDS) on at least three separate days	
Hartley and Hassani (1994)	Self-report study	DBI	755 Australian participants; 184 truck drivers with high violation involvement (HVI) (37%) and 151 with low violation involvement (LVI) (30%) 183 car drivers with HVI (37%) and 237 (47%) with LVI	PCA revealed a six-factor solution. HVI car drivers scored higher on AGG than LVI car drivers but truck drivers did not differ. For DIS, both groups of LVI drivers scored higher than HVI counterparts. Truck drivers reported that driving is more stressful than car drivers did and HVI truckers reported that driving more stressful than LVI truckers, but this relationship was reversed for car drivers	The dependent variables were composites of accidents. Confidence of control predicted accidents and convictions

<i>Reference</i>	<i>Method</i>	<i>Scale</i>	<i>Participants</i>	<i>Results</i>	<i>Comments</i>
Hennessy and Wiesenthal, (1997)	Field study	DBI	27 Canadian student sample and 13 working participants (50% males); mean age = 28.85	Significant interaction found between the GEN and levels of traffic congestion with greater levels of stress reported in high congestion conditions. High GEN scorers showed even further elevation in state stress than those who were lower in GEN, under similar conditions	First field study to validate the DBI but participants studied during only one trip
Hennessy and Wiesenthal (1999)	Field study	DBI	60 Canadian commuters (50% males); mean age = 28.80	GEN was a predictor of state driver stress in both low congestion and high congestion road conditions. State driver stress in low congestion was predicted by time urgency and GEN in low congestion	Transactional nature of driver stress confirmed in field trials
Hennessy et al. (2000)	Field study	DBI	56 Canadian commuters (50% male); mean age = 26.50	GEN correlated with the State Driver Stress Questionnaire (SDSQ) and the Survey of Recent Life Experiences (SRLE). GEN contributed positively under low congestion and hassles by GEN interaction under high congestion. Hassles exposure moderately increased state driver stress for high GEN drivers, but reduced state driver stress for medium and low GEN drivers	Only one commute trip investigated
Hennessy et al. (2004)	Self-report study	DBI	192 Canadian commuters (36% male); mean age = 25.83	High GEN drivers reported greater mild driver aggression than low stress drivers. Male drivers reported greater frequency of past violent driving behaviors than female drivers and high GEN drivers reported greater violence than low stress drivers	The DSI scores are associated with more extreme driver violence
Hennessy and Wiesenthal (2001)	Field study	DBI	192 Canadian commuters (36% male); mean age = 25.83.	Gen positively correlated with Self Report Driver Aggression and negatively correlated with driver Age. GEN predicts mild driver aggression and driver violence. High GEN drivers were also found to report elevated incidents of past driving violence compared to low GEN drivers	Female sample was slightly younger and less experienced than the male sample
Hill and Boyle (2007)	Self-report study	DBI	914 American drivers (60% male); 80% commuted to work daily	18 driving scenarios (for freeway and non-freeway driving) were grouped using factor analysis to group driving conditions that have similar stress ratings using the DBI. Four factors revealed that Weather-related conditions and interactions with other drivers were skewed toward higher stress levels, while performing driving tasks and visibility-related conditions were skewed toward lower stress levels. Drivers found weather-related conditions and interactions with other drivers to be more stressful than contending with limited visibility	Findings show that stress depends on driver characteristics and the specific driving environment
Kontogiannis (2006)	Self-report study	DBI	714 Greek participants (66% male)	DSI and DCQ factor analyzed for a Greek sample supporting the main factor structure of AGG, DIS and AL.	Drivers high in AGG were more likely to be caught speeding and reported more accidents

(continued)

Table 1 Driver behavior inventory (DBI) review (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Lajunen et al. (1997)	Self-report study	DBI	Sample 1: 201 Australian student participants (35% male); mean age = 30.5; mean driving experience = 11.7 years Sample 2: 203 Finnish student participants (32% male); mean age = 24.3; mean driving experience = 5.3 years	Males scored higher than females on and AGG was negatively correlated with age. DIS increased with age and decreased with driving experience. High AGG drivers were more likely to engage in CONF and DIS was associated with self-criticism For sample 1, DIS was negatively associated with Driver Social Desirability Scale (DSDS) Driver Self-Deception (DSD). AGG was negatively associated with DSDS-Driver Impression Management (DIM). AL was positively correlated with DSDS-DSD, DSDS. For sample 2, DIS was associated with DSDS-DIM, DSDS-DSD. AGG was negatively correlated with DSDS-DSD and DIM. AL positively correlated with all of the study variables. In the Finnish data, AL had a stronger correlation with DIM than DSD, but in the Australian data AL correlated with DSD, but not with DIM.	DBI factors related to biased driver perceptions
Lajunen et al. (1998)	Self-report study	DBI	Sample 1: 201 Australian student participants (35% male); mean age = 30.5; mean driving experience = 11.7 years. Sample 2: 203 Finnish student participants (32% male); mean age = 24.3; mean driving experience = 5.3 years	AGG correlated negatively with safety skills for both samples. AL correlated with safety skills and perceptual-motor skills in sample 1. DIS had a strong negative correlation with perceptual-motor skills for both samples and correlated negatively with safety skills for sample 1. Speed was negatively related to DIS, but positively related to AGG and AL. DIS, AGG and AL had a significant effect on evaluations of perceptual-motor skills. AGG predicts Safety Motives	Correlations between the DBI scales and driving and personality variables were similar in both countries
Lajunen and Summala (1995)	Self-report study	DBI	113 Finnish student participants, mean age = 23.9 years (28% male); mean driving experience = 5.2 years	Safety motives negatively correlated with AGG and skill was positively correlated with AGG and negatively correlated with the DIS. DIS predicts skill ratings and AGG predicts safety motive scores. AGG correlated with the Externality measured by the Montag Driving Internality and Driving Externality Scales (MDIE)	Neuroticism positively correlated with AGG and DIS confirming previous studies
Liu and Lee (2005)	Field study with instrumented vehicle	DBI	12 Taiwanese participants (50% male); mean age = 35.2; all participants had at least two years driving experience	High AGG and low AGG drivers drove across intersections with or without car-phone. High AGG drivers more likely to approach stop line at a constant speed and brake more intensely and accelerate after the traffic lights than drivers low on AGG. High AGG drivers had 23 instances of high-risk driving including amber-light running tailgating; weaving in and out of traffic; improper passing; passing on the shoulder; improper	A small sample size limited statistical power

(continued)

Table 1 Driver behavior inventory (DBI) review (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Lucas and Heady (2002)	Self-report study	DBI	125 American participants (30% male); mean age = 36.0	lane changes; failure to yield and running stop signs and red lights Time urgency and commute satisfaction was measured via self-report. Commuters who had flexible scheduling reported lower levels of GEN than commuters without flextime	Only one commute trip used when asked to complete the questionnaires
Matthews (1996)	Driving simulator study	DBI	80 British participants (50% males) aged 18–30.	Three significant interactive effects on reaction time were found between DIS, stress condition and road curvature. Significant interactions were also found between DIS and task combination and the stress manipulation were moderated by individual differences in stress vulnerability, assessed by DIS. High DIS drivers under stress showed slower RT, reduced cuing and increased heading error. The data show some correspondence between these effects on objective performance and subjective response to stress. High DIS was associated with a maladaptive pattern of increased cognitive interference under stress	Supports the effort regulation hypothesis, that driver stress may lead to insufficient effort or active control of performance when task demands are low
Matthews and Desmond (1998)	Driving simulator study	DBI	256 British participants (50% male); mean age = 20.9	DIS and FP correlated positively with all fatigue scales, pre- and post-task. AGG was positively associated with pre- and post- boredom, and pre- and post-muscular fatigue. AL was negatively associated with pre- and post- boredom, pre-malaise, pre-muscular fatigue and positively associated with post-malaise. AGG positively correlated with psychoticism and DIS was positively associated with neuroticism. FP was negatively associated with extraversion and positively associated with neuroticism. FP was positively associated with pre- and post-disengagement, distress, and physical fatigue scores; AGG was positively associated with pre-disengagement, distress and physical fatigue scores, and post-disengagement; DIS was positively associated with pre- and post-distress, physical fatigue, and post-disengagement scores. AL was negatively associated with pre- and post-disengagement, post- distress and pre-physical fatigue scores. AL was a significant predictor of pre-disengagement and pre-physical fatigue; AGG and FP were significant predictors of pre-distress and of post- disengagement.	DIS and FP were the most consistent predictors of greater fatigue

Table 1 Driver behavior inventory (DBI) review (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Matthews et al. (1991)	Self-report study	DBI	Study 1: 159 British participants; mean age = 33.0. Study 2: 44 British participants; mean age = 43.0. Study 3: 49 British participants; mean age = 27.0. Study 4: 50 British commuters; mean age = 41.0.	Study 1: Age correlated negatively with AGG, IO, OT and GEN and positively correlated with AL. Neuroticism positively correlated with AGG, DIS and GEN. Psychoticism positively correlated with AGG and GEN and Extraversion correlated with AGG and OT. Speeding conviction associated with lower DIS, IO, OT and AL. Study 2: Age positively correlated with GEN. DIS, AL with frequency of hassles. AGG associated with indirect aggression, irritability verbal expression of aggression and total score. AL positively correlated with negativism and GEN positively associated with irritability and total score. Study 3: Sustaining attention negatively associated with DIS and GEN and positively associated with AL. Absent-minded memory failures correlated with GEN. Efficient processing of auditory stimuli negatively correlated with DIS. Efficient attention to others in social situations positively correlated with AL. Study 4: DIS negatively correlated with tense arousal and hedonic tone. GEN associated with energetic arousal and tense arousal.	GEN AGG and OT associated with minor accidents
Matthews et al. (1993)	Driving simulator study	DBI	61 participants	Three types of driving situation: (1) open-road tasks; (2) following tasks; and (3) overtaking tasks. AGG highly correlated with risk-taking only in overtaking studies. Drivers high on AL paid better attention to hazards	
Matthews et al. (1998)	Driving simulator study	DBI	Study 1: 75 British participants; mean age 44.20 (60% male) Study 2: 65 British participants; mean age 37.40 (50% male) Study 3: 65 British participants; mean age 36.90 (51% male) Study 4: 93 British participants; mean age 22.7 (50% male)	Positional variability associated with DIS in study 1. In study 2, mean speed positively associated with AL and Attention RT negatively associated with AL. Attention (distance) was positively associated with AL and AGG negatively associated with mean distance. In study 3 and 4, positional variability positively associated with DIS. In study 4, simulator errors positively correlated with DIS. AGG positively correlated with mean speed, overtakes, high-risk overtakes, and errors. DIS was negatively associated with ability, judgement, and skill and AL positively associated with ability, judgement, and skill. Age was significantly correlated with AGG and females scored higher on DIS than males. AGG associated with pre-drive tension in Sample 1, pre-drive depression in Sample 4, post-drive energy in Sample 4 and post-drive depression	Results broadly consistent with predictions according to the transactional model of driver stress

Table 1 Driver behavior inventory (DBI) review (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Matthews et al. (1996)	Driving simulator study	DBI	80 British participants (51% males); mean age = 20.9; mean driving experience = 3.4 years	in Sample 4. DIS was positively associated with pre-drive tension in Sample 1, post-drive tension in Sample 1 and post-drive depression in Samples 1 and 4. AL positively associated with energy in Sample 4. High-DIS drivers showed impaired control on straight roads but not curves. High-DIS drivers adapted to high levels of demand, but may be at risk of performance impairment when task requires relatively little active control.	Driving performance varies according to task parameters and individual differences
Matthews et al. (1999)	Self-report study	DBI	510 Japanese participants (50% male); mean age = 36.7	Males and younger drivers score higher on AGG OT and DIS and high scorers rated driving demands higher than low scorers. AGG was the strongest predictor of accident involvement, speeding conviction and other convictions.	Similar factor structure in Japan. AGG the strongest predictor of accident involvement
Maxwell et al. (2005)	Self-report study	DBI	245 British student participants (46.5% males); mean age = 32.44.	Triangular relationship reported between traffic violations, Propensity for Angry Driving Scale (PADS) and AGG. Drivers high in AGG are more likely to commit violations such as speeding and running red lights than their non-aggressive counterparts. Frustration experienced when slowed by other drivers	University students and staff participated
Shamoa-Nir and Koslowsky (2010)	Field study	DBI	226 drivers from Israel (23% male); mean age = 29.0; mean driving experience = 10.27 years	Participants observed driving their cars. Drivers high on DIS reacted emotionally when coping with stress.	Drivers observed as they entered a parking lot and may not be representative of everyday driving
Taubman-Ben-Ari (2008)	Self-report study	DBI	290 conscripts from Israel (53% male); mean age = 19.52 and at least 1 year of driving experience	Self-report measures assessed the perceived costs and benefits of driving, driver self-image, and self-efficacy as a driver. Factor analyses revealed four benefit factors and four costs and four self-image factors. Higher perception of benefits and costs were related to a higher AGG and Self-image of an impulsive driver related to higher AGG. Self-images of a cautious and a courteous driver related to lower AGG. High AL positively correlated with perceived benefit of sense of control, and negatively with perceived costs of distress and life endangerment. DIS inversely associated with perceived benefit of pleasure, and positively related to perceived costs of distress, damage to self-esteem, annoyance, and life endangerment.	DBI factors associated with costs and benefits of driving in an expected direction
Taubman-Ben-Ari et al. (2004)	Self-report study	DBI	328 Israeli participants (32% male); mean age = 31.78	A self-report scale constructed adapting DBI items and other scales to create four driving styles called the multidimensional driving style inventory (MDSI). Factor analysis revealed 8 main factors,

Table 1 Driver behavior inventory (DBI) review (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
				representing dissociative, anxious, risky, angry, high-velocity, distress reduction, patient and careful driving	
Van Rooy et al. (2006)	Self-report study	DBI	322 American Psychology undergraduates (26% male); mean age = 22.12	Construct validity of the DBI showed high correlations among AGG and the Driver Anger Scale (DAS) and Driver Vengeance Questionnaire (DVQ) providing evidence for convergent validity. DBI predicted traffic violations but this was not found for the DAS or DVQ	A confirmatory factor analyses failed to demonstrate discriminant validity between the scales
af Wählberg (2010)	Self-report study	DBI	7522 British participants in wave 1 (59% males; mean age = 21.7). 5633 participants in wave 2 = (59% males; mean age = 21.7)	Significant associations for offender drivers in waves 1 and 2 were found between AGG and self-reported collisions and $r = 0.50$, $P < 0.001$ and penalty points ($r = 0.50$, $P < 0.001$)	Significant associations between AGG and self-reported collisions for offender drivers
Wickens and Wiesenthal (2005)	Self-report and field study	DBI	42 Canadian participants (69% male)	Trait driver stress measured using GEN and participants completed the State Driver Stress Questionnaire (SDSQ) and the Job Stress Survey (JSS) to assess time urgency and perceptions of control during commute in a safe parking space. Time urgency negatively influenced cognitive appraisal of a stressful situation, leading to increased tension and possibly more aggressive driving behavior	High and low traffic congestion studied
Wickens et al. (2015)	Field study	DBI	170 undergraduate students (41% male); mean age = 23.80	GEN a significant predictor of vengeance measured by the Driving Vengeance Questionnaire (DVQ)	Vengeance scores were somewhat low across the sample

and driving history in an expected direction. Field studies have tested the predictive validity of the DBI versus experienced stress in actual driving situations (Hennessy and Wiesenthal, 1997, 1999; Hennessy et al., 2000), showing that the DBI scales are fairly strongly associated with how people react when driving in congested areas. The experimental studies using driving simulators have identified more precise effects of the DBI/DSI dimensions on driving and task performance in a controlled environment. These findings complement those from self-report and field studies. Collectively, the studies reviewed here reveal that different stress vulnerabilities elicit qualitatively different patterns of stress response and impact on driving performance. These findings will now be explored in more detail below.

Aggression (AGG)

This review shows that high AGG drivers tend to be motivated toward maintaining mastery over other drivers (Matthews, 2001b). High AGG drivers tend to appraise other drivers as hostile, and to cope confrontationally. This cognitive style is associated with both anger and dangerous driving. Anger has been investigated via correlational studies of AGG and simulator performance. Matthews et al. (1998a) conducted several experiments in which performance was assessed in different contexts: driving on an open-road with no other traffic, following a lead vehicle with overtaking prohibited, and driving in slow-moving traffic with opportunities to pass. These studies showed that AGG related to performance in the overtaking context only. In two studies, high AGG drivers drove faster, committed more errors and executed more high-risk overtakes with implications for the context-dependence of AGG effects on driving performance. The transactional model implies that the cognitions typical of aggression are likely to be elicited especially by the close proximity of other drivers, or by impedance due to factors such as congestion. Matthews et al. (1998b) showed that, when permitted to pass slow-moving cars, high AGG drivers drove faster, committed more errors and executed more high-risk passes. Although, AGG did not relate to speed in open-road driving suggesting that risky behaviors may be an outcome of a confrontive coping strategy. This hypothesis is confirmed with studies of passing behaviors (Emo et al., 2004, 2016) and further supports the

Table 2 A review of the driver stress inventory and the driver coping questionnaire

<i>Reference</i>	<i>Method</i>	<i>Scale</i>	<i>Participants</i>	<i>Results</i>	<i>Comments</i>
Bergomi et al. (2017)	Salivary-amylase and cortisol study	DSI	42 Italian bus drivers (88% male); mean age = 40.0; mean length of service = 10.5 years	Cortisol levels were positively correlated with FP at the middle of the work-shift and with AGG at the end of a day off. At the end of the work-shift, cortisol levels were negatively correlated with HM) and salivary amylase was positively correlated with TS	The only physiological study to validate the DSI scales
Besharati and Kashani, (2017)	Self-report study	BDBI	107 Persian bus drivers; mean age = 41.9; length of service mean = 15.1 years	Factor structure of the bus driver behavior inventory (BDBI) replicated. The odds of crash involvement decreases by 51%, for each one-unit improvement in HM. For each one unit increase in the RD score, the driver would be 3.2 times more likely to be involved in a crash and the odds of crash involvement would decrease by 51% and 45%, for each one-unit improvement in the FP and TS respectively	HM, RD, FP, and TS predict bus crash involvement
Danaf et al. (2015)	Driving simulator study	DSI	96 Lebanese student participants	State anger and AGG effects found at a specific time period by the occurrence of frustrating events	No interactions with other vehicles studied
Desmond and Matthews (2009)	Field and driving simulator study	DSI and DCQ	Study 1 = 58 Australian long-haul male truck drivers; mean age = 37.09; mean driving experience = 15.08. Study 2 = 104 (42% male); mean age = 32.1; mean driving experience = 12.6 years	DSI and DCQ predictive of state response to driving, and the association between FP and post-drive fatigue found study 1 and 2. Truck drivers apparently resilient to fatigue experienced increases in both fatigue and emotional and cognitive stress symptoms that suggests a risk of performance impairment. Shorter simulator drives in Study 2 did not elicit these reactions in all drivers. FP predicted a range of subjective state variables and also predicted change in fatigue, controlling for individual differences in pre-drive state. DIS and AGG also predicted post-drive fatigue and stress dimensions. FP was the most reliable DSI predictor of fatigue state change, whereas DIS related to cognitive interference, and AGG to anger	Results add to the validity of the DSI as a predictor of post-drive subjective states in both real and simulated driving
Desmond et al. (2001)	Field study	DSI	Study 1: 58 American male truck drivers; mean age = 37.09 Study 2: 104 drivers (41% male); mean age = 32.10	FP positively associated with pre-drive tense arousal, task-induced fatigue and anger. FP also associated with cognitive interference, and negatively associated with hedonic tone and positively associated with	High FP drivers may be at risk from fatigue during both prolonged and relatively short driving trips

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Dorn (2005)	Driving simulator study	DSI and DCQ	53 British male police drivers; mean age = 36.7; mean driving experience = 18.37 years	post-drive measures. High FP drivers in both studies showed elevated levels of state fatigue, tension, unpleasant mood and task-related cognitive interference. HM significantly associated with reduced speed when passing a hazard and a significant correlation between speed at passing the hazard and CONF. Proximity to the hazard was positively correlated with TF. Drivers who crossed the center line at potentially unsafe locations scored higher on DIS compared with police drivers who crossed the center line at safer locations. Drivers who crossed the center line at unsafe locations scored higher on TS	Results add to the validity of the DSI for a police driver group
Dorn and Gandolfi (2008)	Self-report study	DSI and DCQ	334 company car drivers (69% male); mean age = 41.26; mean driving experience = 18.94 years	The DSI and 40 items based on in-depth interviews with drivers at work and a literature review of the risks of driving for work were administered along with the DCQ and the DSDS (Driver Social Desirability Scale; Lajunen et al. 1997). The DSI plus additional items were subject to a PCA revealing 6 factors explaining 46.31% of the variance. Five factors were largely replicated from the DSI – AGG, TS, and HM but FP reversed to reveal a Fatigue Resistance factors (FR) and DIS reversed to form an Enjoyment of Driving factor (ENJ). An additional factor labelled Work Related Risk (WRR) describing risk taking when under time pressure. The DCQ PCA replicated the original 5 factors explaining 50.44% of the variance. WWR positively correlated with AGG, TS, and CONF and EF and negatively correlated with FR and TF	Drivers with two or more crashes reported higher levels of AGG compared with those with 1 or no accidents. Drivers with three or more crashes reported higher levels WRR compared with drivers with two crashes or less
Dorn and Garwood (2005)	Self-report study	DSI and DCQ	Study 1: 45 British bus drivers (98% male); mean age = 43.5. Study 2: 315 bus drivers took part: 297 males and 18 females, aged between 19 and 71 (mean age 46.3)	Factor analyses of the DSI and items generated from interview with bus drivers revealed 7 factors named the bus driver behavior inventory (BDBI) included FP, HM Relaxed Driving (RD), Patient Driving (PAT), Anxious Driving (ANX),	Lower HM and PAT was correlated with blameworthy incidents. EV, ANX and AV predicted blameworthy incidents

(*continued*)

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Dorn et al. (2010)	Driving simulator study	DSI and DCQ	943 British bus drivers (87% male); Study 1: 315 drivers; mean age = 46.3; length of service = 8.9 years. Study 2: 557 drivers; mean age = 46.5; length of service = 8.9 years. Study 3: 71 trainee bus drivers; mean age = 36.0	TS, Incident Inevitability (II) and Evaluative Coping (EV). Blameworthy incident-involved bus drivers scored lower on HM and patient driving (reversed AGG). New factors were similar to the original DCQ factors. Blameworthy incident-involved drivers scored lower on EV and higher on ANX and AV Six factors from DSI and four factors from DCQ were confirmed in a PCA for Study 1. Study 2 test-retest correlations for all the BDRI components ranged from 0.68 to 0.86. HM negatively correlated with all crashes, all responsible crashes and sole responsible crashes. FP correlated with all crashes and EV negatively associated with all crashes and solely responsible crashes. For Study 3, trainees were tested on three simulator drives EF and AV associated with a deterioration of driving performance when under time pressure. AV was consistently and significantly associated with celebration across all drives	Higher HM predicts lower crash involvement. FP positively correlated with all crashes. EV negatively associated with all crashes and solely responsible crashes
Emo et al. (2016)	Driving simulator study	DSI and DCQ	112 American students (36% male); mean age = 20.90; mean driving experience = 5.02 years	AGG positively correlated with CONF. DIS was positively associated with EF and TF. HM positively associated with TF. TS was correlated with CONF and RE and negatively associated with TF. FP was positively correlated with EF. AGG correlated with the UWIST Mood Adjective Checklist (UMACL) anger scale and DSSQ factors of worry and distress. DIS correlated with worry and distress. HM was associated with worry and FP was positively associated with distress and negatively associated with Task Engagement. DIS was positively correlated with distance performance index and negatively associated with distance to oncoming and passes. HM negatively associated with passes and TS positively associated with passes and distance	Individual difference in driver stress responses and risk taking are confirmed

(continued)

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Emo et al. (2004)	Driving simulator study	DSI and DCQ	112 American college students (36% male); mean age = 20.1	AGG and DIS correlated significantly with the Dundee State Stress Questionnaire (DSSQ) post-task distress and worry; FP was associated with high distress and low task engagement. HM correlated positively with worry and DIS correlated with all three "risk-taking" indices of performance: mean distance to lead vehicle at initiation of pass, mean distance to oncoming vehicle. HM was negatively associated with passes and TS was negatively associated with mean distance to lead vehicle at initiation of pass and passes. AGG was associated with post-task anger. CONF, EF, RE and AV was positively associated with the DSSQ post-task worry factor. EF was positively associated with distress and negatively with TF. EF was a significant predictor of post-task worry and CONF was correlated with the three "risk-taking" indices of driving performance and passes. CONF was associated with AGG and post-task anger	Dispositional coping factors predicted risk-taking behaviors, such as frequent passing and were not mediated by situational coping. This suggests that emotions during driving may shape habitual behavioral styles
Funke et al. (2007)	Driving simulator study	DSI	168 American undergraduate students (41% male); mean age = 20.37; mean driving experience = 4.95 years	Pre-task DIS was related to distress and worry and task engagement. Post-task DIS was associated with distress, worry and workload and with distress in the free driving condition; with distress in the lead following condition; and with distress, worry and workload in the automation condition, although it failed to predict performance	Adds to existing personality work suggesting that automation may have unexpected effects on worry in stress-vulnerable drivers
Gandolfi and Dorn (2005)	Self-report study	DSI and DCQ	333 British police drivers (82% male); mean age = 36.17; mean driving experience = 10.81 years	Administered DSI and interview-based items to police drivers seven factor structure established a new inventory called the Police Driver Risk Index (PDRI). The PDRI factors were HM, AGG, TS, Fatigue Resistance (FR), Risk inevitability (RI), Enjoyment of driving (ENJ) and Anxious driving (ANX). Three coping Factors replicated from the DCQ and 2 socially desirable responding factors (partially replicated from the DSDS)	Most DSI factors retained and additional factors emerged for a police driver sample

<i>Reference</i>	<i>Method</i>	<i>Scale</i>	<i>Participants</i>	<i>Results</i>	<i>Comments</i>
Garwood and Dorn (2003)	Self-report study	DSI and DCQ	543 British bus drivers (93% male); mean age = 45.0	AGG, FP and HM retained in factor analyses for bus driver sample and two additional factors were defined as Safe/Cautious Driving with TS items loading negatively and Enjoyment of Driving loadings in the opposite direction. Five factors were confirmed equivalent to the original DCQ	First study to develop a bus driver version of the DSI
Hennessy et al. (2016)	Self-report study	DSI	206 Canadian student sample (46% male); mean age = 22.57; mean driving experience = 6.23 years	Two versions of a simulator-based video of a vehicle crossing the center line into the path of oncoming victim vehicle were created by varying the time period elapsed prior to and following a near collision. For the "early" timing condition, the offending vehicle traveled without incident for 30s prior to the near collision. In the "late" timing condition the offending vehicle traveled for 4 mins without incident prior to the near collision. A Primacy Effect dominance in driver judgments for the early group was moderated by high HM drivers ratings. Primacy may be due to increased vigilance to early stimuli under a stressful condition, and high HM led to more negative ratings of "riskiness"	HM score exaggerated negative evaluations in the Early Timing group
Hoare (2001)	Self-report study	DSI	54 Australian bus drivers (98% male); modal age range = 40 - 59 years. 72% employed full-time with 9+ years driving experience (69%)	AGG, DIS, FP, TS, CONF and EF predictors of Need for Recovery, Job-Related Affective Well-Being and Physical Symptoms. AGG the single best predictor of Job-Related Affective Well-Being, whilst FP was the most reliable predictor of Need for Recovery	The DSI associated with work related factors
Kashani and Besharati (2019)	Self-report study	BDBI	177 Iranian male bus driver participants; mean age = 41.7; mean driving experience = 11.9 years	BDBI factors based on the DSI and DCQ (Dorn et al., 2010) were replicated. Older drivers were significantly more prone to fatigue and greater levels of Relaxed Driving compared with younger drivers.	HM predicted bus drivers' crash involvement
Machin (2001)	Self-report study	DCQ	108 Australian male bus drivers aged between 30 and 60 and most drivers had been working for at least 9 years	Evaluation of a fatigue management program using the DCQ found that higher scores on CONF were associated with greater job dissatisfaction and higher scores on TF were negatively associated with length of service. High EF positively associated with kilometers driven and number	More experienced employees reported similar outcomes to new employees

(continued)

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
				of traffic fines. High RE scores associated with number of hours spent driving and with lower job dissatisfaction. High AV scores also positively associated with a greater number of hours spent. Higher scores on the Job-related Affective Well-being Scale were strongly related to increased TF and RE. Lower Affective Well-being was strongly associated with greater reported use of CONF and EF	
Machin and Hoare, (2008)	Self-report study	DCQ	159 Australian bus driver participants (98% male).	Weekly Driving Hours positively correlated with CONF and AV. CONF and EF accounted for 5% of the variance in Need for Recovery. CONF was a predictor of Physical Symptoms. EF and RE were predictors of Positive Affect. CONF and EF were predictors of the variance in Negative Affect	Low response rate from an initial 500 coach drivers contacted
Matthews et al. (1996)	Self-report study	DSI and DCQ	602 participants Sample 1: British at work drivers (48% male) Sample 2: British students (48% male) Sample 3: American students (36% male)	Alpha coefficients for the scales ranged from 0.73 - 0.87 in British samples, and from 0.69 to 0.85 in the US sample. Highest positive correlations between AGG and TS and between DIS and FP. Age was positively correlated with HM and negatively correlated with TS and DIS. Males were higher than females on TS but females had higher scores on DIS and FP. Positive correlations found between AGG and CONF, between DIS and EF and between HM and TF. TS was also strongly correlated with CONF and both TS and AGG were related to reduced TF. AGG, DIS, FP and TS were related to Neuroticism. Openness positively correlated with TS and negatively correlated with DIS; extraversion negatively correlated with HM and DIS and positively correlated with TS	
Matthews et al. (1997)	Self-report study	DSI and DCQ	Sample 1: 339 British working drivers (48% male) Sample 2: 244 British student (51%) Sample 3: 219 American students (36% male)	A principal components analysis of the 83 DSI stress items was conducted and five factors extracted. DSI scores were compared (1) in accident involved and non-involved groups, and (2) in convicted and non-convicted groups. In the British sample, accident involvement related to higher	The study uses data from Matthews et al (1996). TS, HM and were associated with higher accidents and convictions

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Oz et al., (2010)	Self-report study	DSI	234 Turkish male drivers, professional and non-professional from four different driver groups (taxi drivers, $N = 69$; minibuses drivers, $N = 63$; heavy vehicle drivers, $N = 64$; and non-professional drivers, $N = 38$)	TS, AGG and lower HM. Convictions were associated with AGG, FP and a trend toward higher TS in the convicted group. In the US sample, both accidents and convictions related to AGG for accidents and convictions, and to TS for accidents. Differences for the relationship between AGG and TS between taxi and non-professional drivers, minibuses and heavy vehicle drivers, minibuses and non-professional drivers, and heavy vehicle and non-professional drivers. The correlations for AGG and FP were significant for the taxi and minibuses drivers and a significant difference was observed in the correlations between AGG and HM for the minibuses and truck drivers	Professional drivers report greater levels of driver stress than non-professional drivers suggesting different types of countermeasures
Qu et al. (2016).	Self-report study	DSI	244 Chinese participants aged between 18-66 (48% male)	Internal consistency coefficients ranged from 0.63 to 0.75. AGG, HM and FP correlated with all of the Driver Behavior Questionnaire (DBQ) subscales ranging from ± 0.17 to ± 0.46. DIS was positively associated with errors and lapses. TS was significantly associated with AGG and errors. AGG and FP were associated with accidents and minor accidents and HM was negatively associated with minor accidents. DIS and FP were negatively associated with mileage whilst TS was positively associated with mileage. Females reported greater levels of DIS and FP and lower levels of HM than male drivers did. Speeding and traffic sign violation offenders reported higher AGG and TS, while drivers with traffic sign violations reported decreased HM compared with non-offenders	AGG and FP scales predicted accidents and minor accidents. Higher HM associated with lower number of minor accidents
Rowden et al. (2011)	Self-report study	DSI	247 Australian employee participants; age ranged from 22 years to 69 years with the majority being male (77.7%)	DSI scales found to have acceptable reliability. AGG, DIS and FP positively associated with DBQ errors, lapses and violations. AGG FP and TS were positively correlated with Violations which was negatively associated with HM. Age was negatively related to all DSI scales except	Driver stress may be reciprocally related to stress in other domains, including work and domestic life

(continued)

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
				HM which was positively related. Gender differences were found for DIS, AGG, FP and HM in the expected direction. AGG and DIS were positively associated with the General Health Questionnaire (GHQ), Job Related Tension Scale (JRTS) and Daily Hassle; FP was positively associated with Daily Hassle and GHQ. Confirmatory factor analysis of the predictor variables revealed two factors related to DSI: negative affect and risk taking which influenced both lapses and errors, and the DSI risk-taking factor had the strongest influence on violations	
Susilowati and Yasukouchi (2012)	Self-report study	DSI and DCQ	35 Japanese participants: older group; mean age = 61.9; older age group; mean age = 69.5. 10 student participants in the young group (50% male); mean age = 23.3	Correlation for DSI and DCQ factors observed only in older drivers. FP was lower for younger drivers than older drivers. Older drivers also had a lower score for TS and AGG. Young drivers scored higher on EF whereas the older group tended to score moderately. For the older driver groups EF was correlated with RE and AV. For the older age group 2 AV was positively correlated with CONF, TF and EF	
Wishart et al. (2017)	Self-report study	DSI	892 Australian employee participants (59% male); mean age = 43	TS predicted all work-related risky driving behaviors taking into account age, gender and work driving exposure. High TS scorers were more likely to conduct unsafe driving behaviors including errors and violations and driving while distracted and fatigued. TS was the strongest predictor and accounted for the largest unique variance of all occupational risky driving behaviours	Variance explained by thrill and adventure seeking in driving error is relatively low (11.5%)
Wohleber and Matthews (2016)	Self-report study	DSI	127 American student participants (49% male); mean age = 20.16	Self-confidence in general driving ability and self-confidence in managing impairments correlated negatively with DIS and FP. Self-confidence in ability to compensate for impairments correlated positively with TS and negatively with HM. Ratings for the above average effect (AAE) were negatively associated with DIS. Additionally, impairment AAE was positively correlated with AGG. DIS	AAE was the significant predictor variable, and HM TS, and FP substantially improved prediction for DBQ errors

(*continued*)

Table 2 A review of the driver stress inventory and the driver coping questionnaire (*cont.*)

Reference	Method	Scale	Participants	Results	Comments
Zhang et al. (2009)	Driving simulator study	DSI	20 participants (50% male); Young group mean age = 20.7; mean driving experience = 5.4 years; Older group mean age = 72.2; mean driving experience = 55.1 years	was associated with reduced confidence on all self-estimation and overplacement High HM and FP associated with reduced speed in the presence of a hazard with velocity ratio correlating with these DSI factors. AGG and DIS did not show any significance with age. Under normal driving conditions, no effect of driver stress on driving behavior was seen	Presence of a hazard or driving under a critical condition has a significant influence on the driver's stress state

transactional model. It seems that dangerous behaviors are more likely to be elicited in interaction with other road users as hostile appraisals trigger impatience and a confrontive coping style, consistent with their higher crash frequency in real life (Matthews et al., 1999b).

Dislike of Driving (DIS)

DIS is associated with negative self-appraisal (Dorn and Matthews, 1995) and emotion-focused coping strategies such as self-blame that generate negative mood states and worries which tend to interfere with task performance. Higher levels of tension, anxiety, unhappiness and worry during both real and simulated drives have been reported (Dorn and Matthews, 1995; Matthews, 1996, 2001). Simulator studies of DIS show how the maladaptive cognitions associated with anxiety, such as emotion-focused coping, may produce performance impairment, especially in threatening environments. DIS correlates positively with variability of lateral position, indicating poor psychomotor control, with control errors and was negatively associated with total overtaking frequency (Matthews et al., 1998). Higher frequencies of driving errors have also been reported by high DIS drivers in self-report studies (Matthews et al., 1997). It appears that high DIS drivers are more behaviorally cautious so that there is little overall impact on safety although negative self-appraisals may divert attention from the driving task, resulting in impaired performance efficiency and behavioral distractibility.

Further studies investigated cognitive factors for effects of DIS on attentional performance, using dual-task methods (Matthews et al., 1996). Drivers performed an additional secondary task and task demands were independently manipulated by varying the curvature of the road (straight vs curved). The results showed the suppression of typical DIS effects under high task demands showing that when task demands are low, high DIS drivers may divert attention onto internal worries. DIS effects on performance were also accentuated following exposure to steering control disruption. Here, DIS was associated with poor control of lateral tracking and poor attention to secondary task stimuli presented on road-signs as they attempted to control a skidding vehicle (Matthews, 1996).

Alertness (AL)/Hazard Monitoring (HM)

The DBI AL factors and the DSI HM factor appear to be more narrow in scope from a stress perspective and relate to a specific style of task-focused coping by actively monitoring for hazards and detecting hazards faster (Dorn, 2005; Matthews et al., 1998; Zhang et al., 2009). AL/HM does not appear to be associated with negative mood or stress states compared with other dimensions (Matthews et al., 1997). AL is associated with safety skills and perceptual-motor skills (Lajunen et al., 1998) and negatively associated with pre- and post-disengagement (Matthews and Desmond, 1998). HM is negatively correlated with self-confidence ratings in ability to compensate for impairments (Wohleber and Matthews, 2016) and associated with reduction in speed when passing a hazard (Dorn, 2005; Zhang et al., 2009); negatively correlated with cortisol levels (Bergomi et al., 2017); decreasing odds of crash involvement (Besharati and Kashani, 2017); more negative evaluations of danger (Hennessy et al., 2016); a lower number of minor collisions (Qu et al., 2016) and bus crashes (Dorn et al., 2010; Kashani and Besharati, 2019).

Kontogiannis (2006) reported that AL increased with age, possibly due to increasing driving experience. However, Westerman and Haigney (2000) found that AL decreased with age perhaps due to an age-related decline in cognitive capacity. Further studies are required to investigate the role of strategy and capacity for different age groups.

Thrill Seeking (TS)

High TS is defined by enjoyment of danger and risk taking. Therefore, negative correlations with DIS have been reported (Matthews et al., 1996). TS has been found to be a significant predictor of violations in the DBQ (Matthews et al., 1997; Qu et al., 2016;

Westerman and Haigney, 2000) and is positively correlated with driving offences (Matthews et al., 1997; Rowden et al., 2011). TS is linked to CONF (Emo et al., 2016) and self-reported accident involvement (Besharati and Kashani, 2017; Matthews et al., 1997) and positively associated with number of passes, risky passes and reduced distance to other vehicles in simulator studies (Dorn, 2005; Emo et al., 2016). For drivers at work, TS also predicts all work-related risky driving behaviors taking into account age, gender and exposure. TS was the strongest predictor and accounted for the largest unique variance of all occupational risky driving behaviors (Wishart et al., 2017). High TS scorers reported unsafe driving behaviors including errors and violations.

Fatigue Proneness (FP)

Initial studies of FP showed that this dimension was a significant predictor of errors and lapses, (Matthews et al., 1997). In subsequent simulator studies, FP effects on performance have been studied primarily through experimental inductions of fatigue by having drivers perform a perceptually and cognitively demanding secondary task concurrent with driving. FP effects were found only when driving straight road sections, rather than curves (Matthews et al., 1996). The deficits shown by fatigued drivers during straight-road driving may reflect difficulties in mobilizing sufficient effort to maintain adequate performance in a monotonous situation, due to loss of motivation. Desmond et al. (2001) found that FP is most predictive of loss of task engagement following a fatiguing or long-duration drive. High FP drivers also showed elevated levels of state fatigue, tension, unpleasant mood and task-related cognitive interference. Matthews (2001) suggests that high FP drivers tend to be motivated toward avoiding discomfort when tired. These processes may be moderated by the driver's appraisal of the need for effort and their willingness to engage in task-focused coping depending on driving task variation demands.

The above studies show that the DBI/DSI measures and predicts individual differences in driver stress and performance. The research to date reveals that drivers are not passively experiencing "stress" due to external demands but are actively evaluating the events they encounter. The appraisal process appears to trigger personal concerns, such as their attitudes toward other drivers, and beliefs about their own driving competence and ability to cope. These kinds of behavior have implications for driver safety. Whilst crashes are difficult to predict, especially with self-report measures (af Wählberg and Dorn, 2015), it is encouraging that correlates of crash involvement with the DBI/DSI scales have been found. Tables 1 and 2 show that the DBI/DSI scales have been found to be correlated with road traffic accidents in several studies (Dorn and Gandolfi, 2008; Dorn et al., 2010; Kashani and Besharati, 2019; Kontogiannis, 2006; Matthews et al., 1991, 1997, 1999; af Wählberg, 2010). Minor crashes were predicted in two studies (Matthews et al., 1991; Qu et al., 2016) and partly replicated in Matthews et al (1996). Cognitive interference may explain the statistical link between stress and crash risk previously described (Matthews et al., 1998). Emotional stress impairs performance by adding to the driving task demands and may divert attentional resources, leading to performance decrements, particularly if the task is demanding.

Driving for Work

It has been well established that driving for work is stressful given that it may require the pressure of driving to schedules, often for long hours and with some form of job performance or delivery targets to achieve. DSI/DCQ Studies have shown that drivers at work are particularly prone to adverse stress and fatigue reactions as summarized in Tables 1 and 2 (Bergomi et al., 2017; Desmond and Matthews, 2009; Hoare, 2001; Matthews et al., 2001; Oz et al., 2010). Intercorrelations have also been found for the driver stress dimensions with general health, job related stress and daily hassles (Machin 2001; Rowden, et al., 2011; Wickens and Wiesenthal 2005; Wishart et al., 2017) suggesting a "spillover" effect. That is, driver stress may be reciprocally related to stress in other domains including work and domestic life and the scales have been found to predict various stress outcomes for professional drivers.

In view of these findings, several studies have called for the administration of the DSI/DCQ to assess individual differences in driver stress and coping (Dorn and Gandolfi, 2008; Dorn et al., 2010; Machin, 2001; Matthews et al., 1998; Rowden et al., 2011). Individual scores can then be used to deliver interventions to develop driver safety-enhancing appraisals and coping responses. In 2005, a fleet version of the DSI and DCQ scales including the DSDS (Lajunen et al., 1997) called the Fleet Driver Risk Index (FDRI) (Dorn and Gandolfi, 2008) was made commercially available to fleet-based organizations on a Cranfield University online platform called DriverMetrics. Since then variants for other professional groups have also been added for profiling professional drivers (police; Gandolfi and Dorn, 2005; bus; Dorn et al., 2010). Coaching interventions to regulate the emotional reactions to driving are used to address maladaptive cognitions, stress responses and coping to mitigate the risk of work-related crash rates. Research to evaluate the effectiveness of this approach using a control group is planned, although many case studies have shown significant reductions in crash rates since implementation. In professional driving settings, this multivariate assessment can also support the hiring of those drivers whose styles of cognition promote safety and thus are less likely to cause vehicular damage and injury and fatal crashes. Based on the research evaluated in this chapter, drivers with adaptive coping styles will probably have fewer personal injuries, cause less property damage, and therefore be a more productive employee.

Conclusion

The data reviewed here suggests an individual driver's propensity toward risk-taking is dependent on a variety of personality-based emotional factors, including enjoyment of risk, risk-taking associated with frustration, impatience and hostility to others and

ineffective coping strategies. About seventy key papers have studied the DBI/DSI/DBQ scales confirming its psychometric properties, stability over time, validity and predictive capacity for driver reactions, performance behaviors, and accidents. Research on its practical application as a driver risk assessment tool for stress management when driving for work is underway and is currently widely used across many countries within large fleet-based companies.

Acknowledgment

I am grateful to Gerry Matthews and Anders af Wahlberg for comments on an early version of this review and to Tetiana Hill for a literature search.

Biography

Dr Lisa Dorn is an Associate Professor of Driver Behavior and Director of the Driving Research Group at Cranfield University. Dr Dorn is also Founder and Director for DriverMetrics, a Cranfield University spin-out company to exploit her research in the design of educational interventions to improve driver safety. Dr Dorn has been a Principal Investigator for nearly three decades on a range of projects on driver behavior.

Introduction to Sustainability and Health in Transportation

Roger Vickerman, School of Economics, University of Kent, Canterbury, United Kingdom; Transport Strategy Centre, Imperial College, London, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Sustainability of transport systems has for some time been largely seen as a question of the impact of transport on the environment both at a global level through greenhouse gas emissions and at a more local level through local air pollution, noise, and visual intrusion. Whilst these issues remain important and at the forefront of much research and an increasingly dominant topic in policy debates, the overall relationship between transport and health has become increasingly important. That transport affects the health of people in a negative way is part of the evaluation of the environmental impacts. But the accessibility of transport to some sections of the population, defined by such factors as age, gender or disability, and hence their access to a variety of activities from employment to leisure to education and healthcare is now an increasing concern. The choice of mode of transport may impact on health; this can be negative through choosing to walk in an environment polluted by traffic or positive through choosing to cycle along a growing network of segregated cycleways. Within modes the growing popularity of e-bikes or e-scooters demonstrates a desire to use cars less, but with some conflicting views on their health benefits, including accident risks.

The articles in this section present a range of views across these topics. All demonstrate the vibrancy of research and the importance of the policy debate at local, national, and international levels and outline the future priorities in both research and policy. Topics covered not only include the various environmental impacts of transportation, both global and local, and their health implications; but also major policy and planning initiatives to improve ways of life such as car-free cities and green space. Social aspects such as access to facilities, social exclusion and the problems facing specific groups of the population are important topics. Rising issues covered include the role of autonomous and connected vehicles and the implications of increased use of electrically powered vehicles, as well as the potential of shared mobility. More philosophical topics such as the concept of human ecology and the rising concern for environmental and transport justice are included as well as the way transport forms a major element in the UN Sustainable Development Goals. Many of the chapters have crosscutting themes with chapters in other sections of the Encyclopedia, especially those dealing with Psychology, Transport Planning and Policy and Safety and Security and readers are invited to explore these to gain a fuller understanding of the issues.

Sustainable Development Goals

The Sustainable Development Goals (SDGs) are a universal call to action to end poverty, protect the planet and improve the lives and prospects of everyone. The Goals were adopted by all United Nations Member States in 2015, as part of the 2030 agenda for sustainable development (United Nations, 2015), which set out a 15-year plan to achieve the goals.

The SDGs are composed by 17 goals and 169 targets, which are integrated and indivisible, global in nature, and universally applicable, taking into account different national realities, capacities and levels of development, and respecting national policies and priorities. The Goals recognize the link between sustainable development and other relevant ongoing processes in the economic, social, and environmental fields.

The SDGs replaced the Millennium Development Goals (MDGs), which started a global effort in 2000 to tackle extreme poverty and hunger. For 15 years, the MDGs drove progress in several important areas: reducing income poverty, providing much needed access to water and sanitation, driving down child mortality, and drastically improving maternal health. Most significantly, the MDGs made huge strides in combating HIV/AIDS and other treatable diseases such as malaria and tuberculosis.

The MDGs were revolutionary in providing a common language to reach global agreement, and its achievements provide the international community with valuable lessons and experience to begin work on the new goals. However, the MDGs only applied to developing countries, while the SDGs apply universally to all UN Member States, and they are considerably more comprehensive and ambitious than the MDGs.

The SDGs were the result of over two years of intensive public consultation and engagement with civil society and other stakeholders around the works, which paid particular attention to the voices of the poorest and the most vulnerable.

The Global Goals

- Goal 1. End poverty in all its forms everywhere
- Goal 2. End hunger, achieve food security and improved nutrition and promote sustainable agriculture
- Goal 3. Ensure healthy lives and promote wellbeing for all at all ages
- Goal 4. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
- Goal 5. Achieve gender equality and empower all women and girls
- Goal 6. Ensure availability and sustainable management of water and sanitation for all
- Goal 7. Ensure access to affordable, reliable, sustainable and modern energy for all
- Goal 8. Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all
- Goal 9. Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
- Goal 10. Reduce inequality within and among countries
- Goal 11. Make cities and human settlements inclusive, safe, resilient, and sustainable
- Goal 12. Ensure sustainable consumption and production patterns
- Goal 13. Take urgent action to combat climate change and its impacts

SUSTAINABLE DEVELOPMENT GOALS

Figure 1 Icons of the SDGs. Source: From United Nations Sustainable Development site un.org/sustainabledevelopment.

- Goal 14. Conserve and sustainably use the oceans, seas and marine resources for sustainable development
- Goal 15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
- Goal 16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
- Goal 17. Strengthen the means of implementation and revitalize the global partnership for sustainable development (**Fig. 1**).

SDGs Monitoring and Reporting

The Sustainable Development Goals are not legally binding. Nevertheless, countries are expected to take ownership and establish a national framework for achieving the 17 goals. Implementation and success rely on countries own sustainable development policies, plans, and programs.

Besides financial implications, the most significant challenge to the universal implementation of the SDGs include capacities for progress monitoring. Actions at national and subnational level to monitor progress require quality, accessible and timely data collection and regional follow-up and review.

The UN provide the Global Indicator Framework for Sustainable Development Goals ([United Nations, 2020a](#)) that allow to monitor and review the 17 goals and 169 targets using a set of global indicators. Governments are requested to develop their own national indicators to assist in monitoring progress.

The follow-up and review process is informed by an annual SDG Progress Report to be prepared by the Secretary-General. The report provides an overview of the world's implementation efforts to date, highlighting areas of progress and where more action needs to be taken.

The SDG Report 2020 states that an estimated 71 million people are expected to be pushed back into extreme poverty in 2020, the first rise in global poverty since 1998. In addition, the effects of COVID-19 pandemic are already visible. The more than one billion slum dwellers worldwide are acutely at risk from the pandemic, suffering from a lack of adequate housing, no running water at home, shared toilets, little, or no waste management systems, overcrowded public transport and limited access to formal health care facilities. ([United Nations, 2020b](#)).

The high-level political forum on sustainable development is the annual meetings playing a central role in reviewing progress toward the SDGs at the global level. The Forum adopts intergovernmentally negotiated political declarations.

In addition, understanding that 65% of the SDGs could not be achieved unless local governments are fully and equitably involved in implementation (UCLG, UN-Habitat, 2020), since 2016 local and regional governments monitor and report progress they have made in localizing SDGs and the other global agendas. In 2018, the city of New York was among the first to produce voluntary local reviews (VLRs), organic self-assessing documents, which aimed to complete the information and data on SDG implementation that national governments are already providing, yearly, at the high-level political forum.

The Decade of Action (2020–30)

In September 2019, the UN Secretary-General called on society to mobilize for a decade of action to accelerate SDGs implementation. The decade of action (2020–2030) is deployed on three levels: global action to secure greater leadership, more resources, and smarter solutions for the SDGs; local action embedding the needed transition in the policies, budgets, institutions and regulatory frameworks of local governments; and people action, including by youth, civil society, the private sector, the media, unions, academia, and other stakeholders.

Health and Development

Health is a cornerstone of development. Ensuring healthy lives and promoting well-being at all ages is essential to global sustainable development. In 2017, only around one third to half of the global population was covered by essential health services. If current trends continue, only 39%–63% of the global population will be covered by essential health services by 2030 (United Nations, 2020b).

Recognizing this interdependence, the SDGs provide an ambitious and comprehensive plan of action for ending the injustices that underpin poor health. Goal 3 is focused on good health and well-being. It takes into account widening economic and social inequalities, rapid urbanization, threats to the climate and the environment, the continuing burden of HIV and other infectious diseases, and emerging challenges such as noncommunicable diseases (NCDs). Also, universal health coverage will be integral to achieving SDG 3, ending poverty, and reducing inequalities.

But health is also part of many of the 17 SDGs' indicators and targets—and, at the same time, action on health-related aspects of these SDGs is essential to achieve many of the targets for SDG 3. Following a research led by the Barcelona Institute for Global Health (ISGLOBAL), at least 48 SDG targets are relevant to urban health, corresponding to 15 SDGs, mainly captured by SDG 3 and SDG 11 on inclusive, safe, resilient, and sustainable cities (Ramirez-Rubio et al., 2019) (Fig. 2).

In this sense, SDGs provide a platform for intersectoral work facilitating a “Health in All Policies” (HiAP) approach. HiAP is based on the recognition that our greatest health challenges—for example, noncommunicable diseases, health inequities and inequalities, climate change, and spiraling health care costs—are highly complex and often linked through the social determinants of health. The social determinants of health are the circumstances in which people are born, grow up, live, work and age, and the wider set of forces and systems affecting these circumstances: for example, economic and development policies, social norms, social policies, and political systems.

In this context, promoting healthy communities, and in particular health equity across different population groups, requires that we address the social determinants of health, such as public transportation, education access, access to healthy food, economic opportunities, and more. While many public policies work to achieve this, conflicts of interest may arise. Alternatively, unintended impacts of policies are not measured and addressed. This requires innovative solutions, and structures that build channels for dialogue and decision-making that work across traditional government policy siloes (WHO, 2014).

Shanghai Declaration on Promoting Health in 2030 Agenda

The outcome of the Ninth Global Conference on Health Promotion (Shanghai, 21–24 November 2016), jointly organized by the Government of China and WHO, was the concise Shanghai Declaration on Health Promotion (WHO, 2016). It was endorsed by the over 1260 participants of the Conference from 131 countries, including 81 ministers and 123 mayors.

The Shanghai Declaration recognizes health and well-being as essential to achieving sustainable development. The principal message is that health is a political issue and, therefore, political commitments are crucial. In this sense, the declaration pretends to provide guidance to UN Member States on how to reflect promoting health into national SDGs responses and how to accelerate action.

Health promotion is about enabling and empowering people, communities, and societies to take change of their own health and quality of life. The declaration highlights three pillars of health promotion: *Good governance*: strengthening governance and policies to make healthy choices accessible and affordable to all; and to create sustainable systems that make whole-of-society collaboration real. *Healthy cities*: creating greener cities that enable people to live, work, and play in harmony and good health. *Health literacy*: increasing knowledge and social skills to help people to make the healthiest choices and decision for their families and themselves.

One of the recommended actions on the healthy cities area is to design our cities to promote sustainable urban mobility, walking and physical activity through attractive and green neighborhoods, active transport infrastructure, strong road safety laws, and accessible play and leisure facilities.

Figure 2 SDGs related to urban health within a HiAP approach (Ramirez-Rubio et al., 2019).

COVID-19 Pandemic's Impact in Global Development

In 2020, the world faced a global health crisis unlike any other. Coronavirus (COVID-19) pandemic spread human suffering, destabilizing the global economy, and upending the lives of billions of people around the globe.

The pandemic shown that in rich and poor countries alike, a health emergency can push people into bankruptcy or poverty; hence what began as a health crisis quickly became a human and socio-economic crisis.

In March 2020, the United Nations Secretary-General, António Guterres, reported how the COVID-19 crisis was likely to have a profound and negative effect on sustainable development efforts. A prolonged global economic slowdown may adversely impact the implementation of the 2030 Agenda for Sustainable Development and the Paris Agreement on Climate Change (United Nations, 2020c).

The most vulnerable, including women, children, the elderly, and informal workers, were hit the hardest. The impact on the environment, on the other hand, was likely to be positive on the short term, as the drastic reduction in economic activity reduced CO₂ emissions and pollution in many areas. However, unless countries deliver on their commitment to sustainable development once the crisis is over and the global economy restarts, such improvements are destined to be short-lived.

The United Nations Department of Economic and Social Affairs (UNDESA) mapped how COVID-19 affected each of the SDGs, from disruption to food supplies (SDG 2) to increased levels of violence against women (SDG 5). This conceptual mapping, while simple, shows the value of the SDGs as a framework for understanding the intersecting flow-on effects of a health crisis (Fig. 3).

While the crisis is imperiling progress toward the SDGs, it also makes their achievement all the more urgent and necessary. It is essential that recent gains are protected as much as possible. A transformative recovery from COVID-19 should be pursued, one that addresses the crisis, reduces risks from future potential crises and relaunched the implementation efforts to deliver the 2030 Agenda and SDGs during the decade of action.

Urban Environment and Health

Cities have a huge responsibility and opportunity to promote healthier urban environments. Urbanization is one of the leading global trends of the 21st century that has a significant impact on health. Since 2007, over half of the world's population live in urban areas, a proportion that is expected to raise 66% by 2050 (UN-Habitat, 2018). As most future urban growth will take place in developing countries, the world today has a unique opportunity to guide urbanization in a way that protects and promote health.

Urban areas will be increasingly critical for achieving all SDGs and integrating the social, economic and environmental goals set forth in the 2030 Agenda. It is, therefore, no surprise that SDGs 3 and 11 are strongly interlinked. Both goals have explicitly targeted improving road safety and air quality. Target 4 for cities directly links to health by aiming to reduce mortality due to disasters. Additionally, all targets of Goal 11 that aim to improve the living and working conditions of people in cities will support the achievement of the health goal.

As an example, 7 million people die every year from exposure to fine particles in polluted air. Air pollution is a major cause of NCDs. Venerable populations are often at risk from a variety of sources, which may expose them to pollutants including vehicle emissions and industrial discharges. In an analysis of data from 3000 cities, 80% of them did not meet the recommended WHO air quality guidelines, a critical parameter being the presence of fine particulate matter, produced mainly by vehicle diesel-engines. The 60% of European cities, 20% of North American cities, and 40% of high-income Asian cities, fail to meet adequate air quality standards (Clos and Surinach, 2019).

Furthermore, the increasing effects of climate change are now very evident. Climate change affects many of the social and environmental determinants of health—clean air, safe drinking water, sufficient food, and secure shelter. According to WHO, between 2030 and 2050, climate change is expected to cause approximately 250,000 additional deaths per year, from malnutrition, malaria, diarrhea, and heat stress. Reducing emissions of greenhouse gases through better transport, food, and energy-use choices can result in improved health, particularly through reduced air pollution.

Effective planning policies may significantly reduce this problem. Urban planning decisions can create or exacerbate major health risks for populations, or they can foster healthier environments, lifestyles, and create healthy and resilient cities and societies.

On the other hand, urban design can help to reduce inequalities both in service provision and health status and lead to more inclusive and productive societies. Bad examples such as limited access, poor quality, or absence of open public spaces or whole districts built without taking into account the need for people to be able to access local amenities by walking drive an increase of NCDs pandemic. Noncommunicable diseases already account for nearly 70% of global deaths each year with rapid and unplanned urbanization being a major factor. Expanding networks for urban public transit, walking and cycling, particularly for vulnerable groups, and having access to more options for safe mobility can increase access to jobs and services, reduce risks of road injury and limit noise exposure (WHO, UNDP, 2016).

The New Urban Agenda

In 2016, the United Nations adopted the New Urban Agenda at the UN Conference on Housing and Sustainable Urban Development (Habitat III). The New Urban Agenda incorporates a new recognition of the correlation between good urbanization and development, and of the fundamental linkages between health and sustainable urban development. It further clarifies the importance of these linkages, and that health is not only about the provision of health care services, but also reflects on decades of experiences and advances in our understanding of how the shape and form of urban development influences the health of city residents (United Nations, 2016).

The New Urban Agenda recognizes that effective urban planning, infrastructure development, and governance can mitigate risks and promote the health and well-being of urban populations. There is, however, a need to further address how specific urban policies can contribute to reducing disease burdens.

Transportation and Health

Transport plays an essential role in our societies and economies. It provides access to jobs, education, services, amenities and leisure, while contributing to economic growth jobs and trade. At the same time, it has an impact on the environment and human health.

Figure 3 COVID-19 affecting all SDGs (United Nations, 2020c).

Figure 4 Rates of road traffic death per 100,000 (WHO, 2018).

Close to a quarter of global greenhouse gas emissions come from transport and these emissions are projected to grow substantially in the years to come, contributing to climate change. Other pollutants, most evidently in many urban centers, directly impact health; casualties and deaths from transport-related accidents are also on the rise (United Nations, 2020d).

Lack of Safety on the World's Roads

Approximately 1.35 million people die each year as a result of road traffic crashes and road traffic injuries are now the leading killer of children and young people aged 5–29 years.

According to the Global Status Report on Road Safety (WHO, 2018) the number of road traffic deaths continues to rise steadily. However, the rate of death relative to the size of the world's population remains constant. When considered in the context of the increasing global population and rapid motorization that has taken place over the same period, this suggests that existing road safety efforts may have mitigated the situation from getting worse.

Middle- and high-income countries reported progress. However, not a single low-income country demonstrated a reduction in overall deaths. In fact, the risk of a road traffic death remains three times higher in low-income countries than in high-income countries. The rates are highest in Africa (26.6 per 100,000 population) and lowest in Europe (9.3 per 100,000 population). In terms of regions, Americas, Europe and the Western Pacific are showing a decline in traffic deaths rates (Fig. 4).

The SDGs, in its target 3.6, call for a 50% reduction in the number of road traffic deaths by 2020. The current progress remains far from sufficient to achieve the target. In the Stockholm Declaration, ministers and representatives of international, regional and subregional governmental and nongovernmental organizations, and the private sector, recognize that SDG target 3.6 will not be met by 2020 and that significant progress can only be achieved through stronger national leadership, global cooperation, implementation of evidence-based strategies and engagement with all relevant actors including the private sector, as well as additional innovative approaches (Third Global Ministerial Conference on Road Safety: Achieving Global Goals 2030, 2020).

Sustainable Transport

The role of transport in sustainable development was first recognized at the 1992 United Nation's Earth Summit and reinforced in its outcome document—Agenda 21. The global attention to transport has continued in recent years. World leaders recognized unanimously at the 2012 United Nations Conference on Sustainable Development (Rio + 20) that transportation and mobility are central to sustainable development. Sustainable transportation can enhance economic growth and improve accessibility. Sustainable transport achieves better integration of the economy while respecting the environment, improving social equity, health, resilience of cities, urban–rural linkages, and productivity of rural areas.

In the 2030 Agenda for Sustainable Development, sustainable transport is mainstreamed across several SDGs and targets, especially those related to food security, health, energy, economic growth, infrastructure, and cities and human settlements.

Sustainable transport plays a fundamental role in overcoming the social exclusion of vulnerable groups. SDG target 11.2 explicitly calls on the international community to work toward sustainable transport for all people: "By 2030, provide access to

safe, affordable, accessible and sustainable transport systems for all, improving road safety, notably by expanding public transport, with special attention to the needs of those in vulnerable situations, women, children, persons with disabilities and older persons.”

It seeks to expand public transportation making it easy for vulnerable groups to use. Good mass transportation and high-density, compact urban design go hand in hand. Efficient planning will result in lower travel times and costs, especially if the right mix of walking and cycling facilities are combined with public transport and rapid transit systems. This must be done in such a way to reduce hazards for pedestrians and cyclists from motorized transport and, has been shown to greatly reduce the prevalence of NCDs. Encouraging less private motor vehicle use, impacts positively on air and noise pollution. Public transport can also help to promote equity in access to employment, educational and social amenities.

Evidence indicates that significant health gains can be made from restricting the use of diesel engines for both commercial and private vehicles in dense urban systems. The exhaust gases are carcinogenic, and emit a greater proportion of small particulate matter, which is associated with increased stroke, heart and respiratory disease, and early death (WHO, 2003).

In Mexico City, the reductions in air pollution resulted in a saving in 6100 days of lost work, together with reduced cases of bronchitis and deaths (WHO, UN-Habitat, 2016). Over the past 10 years, improved bus rapid transport systems serving around 1 million passengers a day, encouraged 10% of the population to leave their cars at home. Additionally, an innovative bike sharing program was developed which was integrated with the metro-rail and bus systems, offering one payment for all. Greater access to parks and green spaces was also made possible.

Providing access through sustainable transport will require advances in three key areas: policy development and implementation, financing, and technological innovation. If rigorous action is pursued in each of these areas, together they will drive change and help individuals, businesses and governments mobilize sustainable transport.

Introduction

Mobility and transportation are fundamental constituents of human life. Both can be interpreted as interdisciplinary concepts that federate ideas and methods from several disciplines and professions. Historically, mobility and transportation are intentional processes that respond to fundamental human needs for secure and safe living conditions including protection from natural threats (e.g., avalanches, droughts, floods, and landslides), human threats (e.g., infectious diseases and warfare), as well as a sustained supply of food and water. The mobility of people goods and services not only responds to these essential needs that protect health and well-being, but also personal and group aspirations that express social status, group identity, and personal wealth, as well as specific kinds of lifestyles and ways of living.

Human ecologists have analyzed the transportation of goods, including commercial trade of agricultural produce in global food system (Dyball and Newell, 2015); and the mobility of humans including migration flows, residential mobility, and mass tourism (Fennell and Butler, 2003). An understanding of impacts of tourism on indigenous populations, land use and natural ecosystems, and local economic development, has been associated with environmental and human health impacts in tourist destinations.

There is a relationship between the viability and sustainability of human groups and the demands that they attribute to the natural resources of their habitat and the hinterlands (Lawrence, 2001). Given that natural and human-made ecosystems are finite, the sustainable uses of natural resources and the accumulation of waste products are only possible if human demands do not exceed flows of energy and matter into and out of ecosystems. During the 20th century there were important technological advances leading to more efficient uses of natural resources and lower levels of ejected waste. However, many have argued that, alone, technological innovation will not lead to sustainable development. This viewpoint is shared by several human ecologists, including the late Barry Commoner (1917–2012), and Stephen Boyden (1925–), as well as the authors of the Report of the World Commission on Environment and Development published in 1987.

There has been a large volume of empirical research on the carbon dependency of the transportation sector, and its large contribution to greenhouse gas emissions and ambient air pollution in cities Nieuwenhuijsen and Khreis (2019). These concerns have included impacts on population health and natural ecosystems in the framework of the Transport, Health, and Environment Pan-European Programme (PEP). From the 1990s, the PEP Secretariat led by the United Nations Economic Commission for Europe (UNECE) and the World Health Organization Regional Office for Europe (WHO-EURO) enlarged the public health framework beyond negative impacts of transportation, such as traffic accidents, to include concerns about relations between population health and lifestyles, notably the lack of physical activity of sedentary populations, especially children and young adults (van Schalkwyk and Mindell, 2018). These subjects can be studied independently from several disciplinary perspectives, as well as by interdisciplinary contributions including the natural and medical sciences, the humanities, and social sciences those that apply a human ecology perspective (Lawrence, 2001). Moreover, the PEP Secretariat has identified and promoted relations with the 2030 Agenda for Sustainable Development, by highlighting the areas where the PEP should intensify collaboration in implementing twelve sustainable development goals (SDGs) (World Health Organization, 2018).

The next section presents core principles of human ecology and distinguishes them from those of general and social ecology. Then principles of human ecology are used to formulate and apply a conceptual framework to analyze the impacts of mobility and transportation on individual, population, and planetary health.

Theoretical Concepts and Framework

Ernst Haeckel (1834–1919), a German zoologist, used the term “ecology” in 1866 to denote a science that studies multiple interrelations between organisms and their surroundings. Since the late 19th century, the term ecology has been interpreted in numerous ways including general, human, and social ecology (Lawrence, 2001).

The term “general ecology” was used by botanists and biologists during the last century to refer to the interrelations between animals, fungi, plants, and their immediate surroundings. The number of contributions about the science of ecology grew from the beginning of the 20th century. Animal and plant ecologists maintain that interactions between organisms and all the components of ecosystems follow principles that refer to their similarities and differences. A community of organisms develops from simple to more complex forms through a sequence of developmental stages known as succession. This term refers to the slow progression of changes in communities of animals and plants owing to changes in climatic, ecological, and geological conditions. This trend may become a climax state: Climax is a dynamic equilibrium state that is determined by the limiting factors of the climate, soil, or other ecological conditions (Pickett et al. 2001). Climax refers to the culmination of the evolution of animal and plant communities that correspond to the optimal development of the biomass with respect to specific ecological conditions. By using an analogy, some ecologists imply that human groups and communities are natural phenomena that develop by slow progression and succession processes. This interpretation means that psychological and social characteristics of human individuals and societies are analogous to biological factors; that competition between human beings is an innate biological process; and that climax is the outcome. The fundamental principles of human ecology challenge this analogy by accounting for the psychological, social, and cultural dimensions of human life including individual and collective behavior that can be adaptive, and capable of sustaining humans in adverse situations (Lawrence 2001).

What is Human Ecology?

Human ecology usually designates studies of the dynamic relationships between humans and the physical, biotic, cultural, and social characteristics of their environment and the biosphere. However, this is not the original meaning of this term which was first used by Ellen Swallow Richards (1842–1911) who founded ecofeminism. In her formulation of Euthenics, she proposed “human ecology” which she defined as a science for better living (Clarke, 1973). From an institutional perspective, human ecology developed in the context of a rapidly urbanizing city after the First World War in the Department of Sociology at the University of Chicago. It was championed by a coalition of researchers from several social science disciplines (including anthropology, demography, geography, psychology, and sociology). These researchers shared a concern about the effects of urban living on the daily life and well-being of the residents, especially minority groups of migrants and low-income households living in cities.

Today, human ecology usually refers to the study of the reciprocal relations between people, their habitat and the environment beyond their immediate surroundings. A conceptual model of human ecology formulated in Lawrence (2001) is reproduced in Fig. 1. This figure is not meant to be a descriptive model of people-environment relations that can provide a complete understanding of a complex and vast subject. Rather, it represents the systemic interrelations between sets of biotic, abiotic, and cultural factors that are combined in any human ecosystem. Hence, it does not concentrate only on specific components because it considers the whole system as the unit of study for people-environment relations. This integrated model can be applied to analyze different geographical areas from the scale of building sites to neighborhoods and cities. It is a synchronic representation of a human ecosystem that is open and linked to others; and it can account for processes that involve mobility and transportation. The model is meant to be applied at different times to explicitly address both short- and long-term perspectives. This temporal perspective can identify change to any of the specific components as well as the interrelations between them. For example, increasing mobility for leisure relies heavily on transportation by motor vehicles that have significant impacts on the consumption of fossil fuels, carbon dioxide emissions, ambient volumes of noise, and concentrations of ozone along major roads. These outcomes are known to have negative impacts on health.

Human ecology is explicitly interdisciplinary. The material and nonmaterial dimensions of human ecosystems, shown in Fig. 1, include genetic patrimony, especially the capacity of the human brain to interpret and transform land and other natural resources into a viable habitat; demographic characteristics such as the size and composition of human populations in mega-urban regions; the social organization of human groups in urban neighborhoods (including kinship relations and household structure); institutions including associations, rules and customs that regulate individual and collective behaviors; the local economy including all consumption and production processes; and, last but not least, the beliefs, knowledge, religion, and values of local populations (Lawrence, 2001).

The conceptual framework shown in Fig. 1 incorporates principles of coaction and coevolution, which should be applied in coordinated ways. These principles express mutual interactions between the ecological, biological, and cultural constituents inherent in human habitats. Consequently, if one of the constituents is changed, then others will also be modified too, because they are directly or indirectly related systemically. This conceptual framework enables an improved understanding of human habitats and contemporary mobility and transportation processes that could impact negatively on them. For example, buildings, villages and cities can be interpreted as metabolisms having systemic properties that are locality specific. The input and output of a system (e.g., a household or a community) can be interpreted as a metabolism, comprising a set of interrelated components, circumscribed by an open boundary with flows of material, and nonphysical entities across it (Dyball and Newell, 2015). The internal processes transform inputs into outputs, which are influenced by feedback loops and other regulatory mechanisms. The applications of this approach include material flow accounts and substance flow analysis. Since the 1990s, manmade ecological systems have been interpreted according to this kind of dynamic representation of material and energy flows which reply on mobility, energy, resources, and transportation. Another application is in the field of public health. Rutter et al. (2017) explain why a complex systems interpretation of health requires an understanding of the many variables that are interconnected.

Figure 1 The holistic and systemic framework of a human ecology perspective showing the interrelations between biotic and abiotic factors, cultural, social, and individual human factors, and artefacts which are delimited by situations, habitats, or large ecosystem Source: [Lawrence, 2001](#)

A human ecology perspective encourages systemic thinking about the increasing incidence of obesity in many countries, extending simple approaches about changing characteristics of food production and consumption processes to include mobility, transport, and other characteristics of lifestyles that are influenced by advertising and marketing. A systemic approach admits that simple cause-effect interpretations that are common in epidemiological research are insufficient to understand the complexity of malnutrition and sedentary living in a rapidly urbanizing world. This means that intervention studies that consider modifying only one variable are unlikely to succeed.

An entry on Human Ecology is included in the UNESCO—Encyclopedia of Life Support Systems explained why the contribution of the Chicago School of Sociology used an inappropriate biological analogy to discuss the life, habitats, and reproduction of humans by comparing them with animals and plants ([Lawrence, 2001](#)). It also noted that the search for simple correlations between biological, economic, and geographical variables that excluded fundamental human values (including ethical values, worldviews, and political authority) could not explain the multiple meanings, geographical layout, and social organization of built environments, especially why different residential areas coexist in the same city.

Human ecology has been challenged owing to criticisms of contributions allied to the Chicago School, mainly between 1920 and the 1950s. These contributions, which could be termed the first generation of human ecology, were supplemented by a second generation, during the 1960s and 1970s. Gerald [Marten \(2001\)](#) explained there are fundamental differences between these two sets of contributions. The second generation includes the seminal contributions of Stephen Boyden, Barry Commoner, René Dubos, and Gerald Young, as well as international research programs, including the Man and Biosphere (MAB) Program coordinated by UNESCO for ecological studies of human habitats. This second generation of human ecology is distinctly different from the first owing to its concern with the “ecologic crisis” from local to global levels of the biosphere. Understanding this crisis requires an interdisciplinary, systemic framework like that applied using multiple research methods in specific cities including Hong Kong ([Boyden et al., 1981](#)). These contributions were the forerunners of recent socioecological systems research, including an increasing number of contributions known today as urban ecology and socioecological systems ([Ostrom, 2009](#)).

The term social ecology is questionable because of its ambiguous connotation. In essence, it does not refer explicitly to the unique capabilities of individual and collective human minds (especially the double articulation of written and spoken language not shared by primates); or human creativity to transform the bounty of nature into artifacts and built environments; or the capacity of the human mind to represent and simulate complex subjects or situations (including future cities). These intellectual capabilities of *homo sapiens* distinguish humans from all other living species (Boyden, 1992). Consequently, the term anthropologic, (rather than sociologic, also applicable to ants, animals and bees, for example) should be used when considering people-environment relations (Lawrence, 2001). This is the way human ecology is interpreted and represented in Fig. 1. It provides an alternative framework to biomedical explanations of individual and population health.

What is Health

Health is a dynamic condition resulting from the interrelations between the biological, chemical, economic, physical, and social environment of humans (Fig. 2). Health is place-based and should be considered as locality specific, not just population specific, and is influenced by changing living conditions. All the components of human habitats should be compatible with basic human needs and full functional activity, including biological reproduction over a long period. A key issue is how transport planning professionals position themselves critically in the context of increasing health and socioeconomic inequalities in cities (Litman, 2013).

Health is a fundamental human right, recognized in the Universal Declaration of Human Rights in 1948. Health is also an essential component of development, vital to a nation's economic growth and internal stability. Today, increasing health care costs, reduced expenditure on public medical services, and lack of universal health insurance, mean that health is increasingly influenced by wealth. Improved health plays a crucial role in reducing poverty (UN Habitat, 2010). In the field of health promotion, health is the capability of individuals and populations to achieve their potential and to respond positively to challenges of daily life. For example, human adaptability, a core concept of human ecology, is an intentional process to sustain health and well-being in situations of radical change, like the threat of individual and societal responses to epidemics, such as coronavirus in 2002-2003 and again in 2019-2020.

Health is an asset, and a resource for everyday life, rather than a standard, or outcome that ought to be achieved. This interpretation is appropriate for research about the multiple interrelations between health, human behavior, built and natural environments, because environmental and social conditions in specific localities do impact on human relations, they may induce stress, and they can have positive or negative impacts on health and well-being. This interpretation of health, founded on core principles of human ecology, implies that the capacity of the medical and healthcare sector to deal with health promotion and prevention is limited. Therefore, close collaboration with other sectors is necessary in order to improve health and well-being.

Health is both an individual and a collective condition that is influenced by decisions made by politicians and professionals in the field of the built environment, including housing, infrastructure, transportation, and land-use planning. These examples also confirm the need to “de-medicalize” common interpretations of sedentary lifestyles, obesity, and other societal disorders in order to account for the crucial role of the built environment, transportation, and active living in influencing health, well-being and life styles. Transportation policy and planning decisions can affect health and well-being in various ways. How people travel influences physical and mental health, including cancer, cardiovascular disease, diabetes, and accidental injury, notably four major causes of mortality (Litman, 2013). Resilience is an interdisciplinary concept used in the behavioral, medical, natural, and social sciences to explain how individuals and groups modify their behavior or components of human ecosystems in order to withstand the negative impacts of adverse conditions on their health and well-being.

Figure 2 This diagram shows 8 sets of interrelated variables that influence health. Interdisciplinary research confirms that the availability and affordability of medical and health services explain only about 10% of those variables that influence health, whereas environmental conditions are estimated to represent about 25% of all variables. Source: © Roderick Lawrence

Ecological research and practice incorporate analyses of natural and human-made ecosystems that influence individual, group, and population health. Pioneers of ecological research on health that apply principles of human ecology include Stephen Boyden, Valerie Brown, Nancy Kreiger, and Anthony McMichael. The postulates of ecological public health emphasize that individual, group, socioeconomic, and environmental variables interact with others (e.g., public policy agendas) across different levels (Rayner and Lang, 2012). A holistic, systemic framework is a basic tenet shared by human ecology and ecological public health. This type of framework should be applied in interdisciplinary and transdisciplinary research. For example, Tretter and Löffler-Stastka (2019) apply core principles of human ecology to analyze relationships between individual and population health, household living, and ambient environmental conditions. Architecture, epidemiology, human ecology, geography, landscape planning, psychology, public health, sociology, statistics, and urban planning can converge and concert using innovative geographical information systems (GIS) and statistical methods to tackle the complexity of this subject. This innovative approach can improve current understanding and promote the application of new knowledge that can be used in policy definition and project implementation that explicitly accounts for health, mobility, and transportation.

Conclusion

The impacts of human societies on biophysical components of the biosphere and on humans themselves have been studied using principles of human ecology during the last 30 years. McMichael (2001), for example, analyzed adaptation processes used to maintain human health in response to negative influences from natural and manmade ecosystems. The term “evo-deviation” refers to a general biological principle that describes living conditions of human and other species that are different from those in their natural habitat. When these differences become large then unpredicted, perhaps irreversible, maladjustments may occur that impact negatively on health and well-being. Some physiological maladjustments during the last 10,000 years include diseases such as typhoid, cholera, smallpox, and more recently coronavirus and ebola.

Human societies have faced many demanding challenges in the context of rapid demographic, financial, political, and technological developments especially during the last two centuries. Today, societies are confronted by complex ecological, energy, and health challenges at local, regional, and global levels. If these challenges are to be confronted effectively, then societies need to address some fundamental issues, including their increasing mobility and greater reliance on transporting goods and services, because these have multiple, sometimes unforeseen environmental, financial, and social consequences, that impact negatively on health and well-being. Some of these driving forces (especially production and consumption processes that damage the ecological and biological components of ecosystems and human health) are challenging the equilibrium of symbiotic relations between human societies, their health and well-being, as well as living conditions provided by their habitat and the biosphere. This challenging situation is explicitly derived from the principle that anthropogenic factors have become major driving forces in the evolution of the biosphere and living conditions on Earth (Whitmee et al., 2015). Human ecology provides a comprehensive framework for understanding and responding to the public health challenges associated with mobility and transportation in a rapidly urbanizing world.

Biography

Roderick J. Lawrence, B. Arch (Hons), MLitt., DSc is Honorary Professor at the Geneva School of Social Sciences (G3S) at the University of Geneva since 2015. He is a member of the scientific advisory board of the Swiss Academies of Arts and Sciences “Network for transdisciplinary research” since 2009. He was Visiting Professor at the International Institute for Global Health at the United Nations University from 2014 to 2016. He was the founding Director of the Certificate of Advanced Studies in Sustainable Development at the University of Geneva from 2003 to 2015.

Introduction

Cities and their transportation systems have been profoundly changed and shaped by cars. At times it appears that cities cater more for cars rather than for citizens. The car is an important part of almost every transportation system that has brought increased access, mobility and convenience, and increased employment opportunities and economic growth. Many cities and their transportation systems have been developed to accommodate car travel as presented in large and continued investments in for example, the construction, maintenance, and rehabilitation of roadways, bridges and parking spaces. In turn, these decisions led to and reinforced lasting changes to land-use patterns such as urban sprawl (Frumkin, 2016). In many cities, car travel and associated infrastructure keep growing, as transportation planning and policy remain demand-driven. Planners tend to predict car travel and provide required infrastructure to facilitate car mobility, underlined by the belief that this mobility boosts the economy, although the role that further road construction plays in the economy is not so clear (Hensher and Button, 2001). This prevailing planning pattern creates a vicious circle that is hard to break as more car infrastructure leads to more car use, and results in less investment in other forms of mobility. In cities, cars are the most space-intensive form of transportation, both during use (Héran and Ravalet, 2008), and when not in use such as when parking (McCahill and Garrick, 2012). For example, cars consume as much as 70% of land in some American cities' downtowns (Crawford, 2000), and the average car spends about 95% of its life parked. The total number of vehicles in the world is estimated at 1.2 billion and projected to increase to 2.5 billion by 2050 (Voelcker, 2020). The investment in car travel and infrastructure has been enormous and tends to receive more financial support, including subsidies, than other modes of transportation.

While car travel brought along many benefits to some segments of the society, it also is responsible for significant adverse impacts on the environment and human health (Khreis et al., 2019; 2016). A recent study conceptualized the linkages between urban transportation and health and found that health impacts can occur through fourteen interrelated pathways; four of which can be beneficial to human health, and ten of which can adversely impact human health; resulting in premature mortality and increased morbidity rates across a wide range of health outcomes (Khreis et al., 2019). These linkages are illustrated in Fig. 1. In particular, relying on the private car for transportation can take up space in cities, reducing the amount of blue and green spaces, which have been both linked to many beneficial health effects. It can also reinforce and increase sedentary lifestyles, resulting in less physical activity which has been linked to many adverse health effects. As compared to active (walking and cycling) and public transportation, car travel results in more contamination, social exclusion, noise, urban heat islands, motor vehicle crashes, air pollution, stress, and greenhouse gases, which result in climate change (Khreis et al., 2019). Car travel can also result in community severance which refers to transportation infrastructure and/or motorized traffic (speed or volume of traffic) which divide places and people, interfering with the ability of individuals to access goods, services, and personal networks (Khreis et al., 2019). These linkages have been reviewed in details elsewhere (Khreis et al., 2019).

The public health burden which results from these linkages is significant, but modifiable. For example, each year, over 1.3 million deaths and 78 million injuries warranting medical care are due to motor vehicle crashes globally (Bhalla et al., 2014). Transportation-related noise and motor vehicle crashes were estimated to result in 1.7% and 1.9% of all-cause premature deaths in Houston, Texas, respectively, which is comparable to the death rate resulting from influenza, pneumonia or suicide in the United States (Sohrabi and Khreis, 2020). Also in Houston, air pollution in the form of fine particulate matter with a diameter of 2.5 micrometers or less (PM_{2.5}) was estimated to result in 7.3% of all-cause premature deaths in 2010, which is higher than the death rate associated with diabetes mellitus, Alzheimer's disease, or motor vehicle crashes in the United States (Sohrabi et al., 2020). In conservative global estimates, 184,000 deaths a year were attributable to traffic-related air pollution (Bhalla et al., 2014). Lelieveld and coworkers estimated that land transport-related air pollution is responsible for one-fifth of deaths from air pollution in the

Fig. 1 Transportation and health conceptual model. Source Khreis et al. (2019).

United Kingdom, the United States, and Germany (Lelieveld et al., 2015), while recent estimates attributed a quarter of new childhood asthma cases per year in an English urban area to traffic-related air pollution (Khreis et al., 2018). Mueller and coworkers estimated that 20% of premature mortality annually is due to reduced physical activity, high exposure to air pollution, noise, and heat; and lack of access to green space in Barcelona, Spain, due to suboptimal urban and transportation planning (Mueller et al., 2017). Even though the mode share of car travel in Barcelona is around 20%, 60% of public space is taken up by car infrastructure such as roads and parking, which could be used in a more beneficial way for human health (BBC News, 2020).

Although it may be difficult to imagine a world without cars, many cities are beginning to shift their transportation solutions away from the private cars and toward active and public transportation, realizing that these latter modes are more environmentally friendly, healthier, and people oriented. The global climate change crisis has also been an important driver and a reason that is often cited by cities in this context. Some cities now refer to such solutions as car-free solutions, which for example include the implementation of car-free city centers, car-free designated areas, and car-free days.

Early Developments Toward Car-Free City Advocacy

A theoretical design for a car-free city of one million people was first proposed by J.H. Crawford in 1996 and further refined in his books, *Car Free Cities* (Crawford, 2000), and *Car Free Design Manual* (Crawford and Dimas, 2009). Later in 1997, the Lyon Protocol was published for the design and implementation of large car-free districts in existing cities (<http://www.carfree.com/lyon.html>). Created during a weeklong conference in Lyon, France, participants envisioned what would be needed to implement car-free districts. This included (1) identifying interested parties, (2) gathering necessary data, for example, on land-use, traffic flows, land ownership, demographics and air, noise, and water pollution, (3) developing preliminary concepts and proposals, (4) facilitating dialogue by building media attention, (5) engaging the political process and building a coalition to support implementing large car-free areas, (6) gradually implementing coherent car reduction measures, (7) engaging with, consulting, and listening to local communities, followed by (8) city planners developing final plans for full implementation. Although not specifically mentioning car-free cities, work by Newman and Kenworthy highlighted many of the problems with car dependence and the benefits of moving away from such development patterns (Newman and Kenworthy, 1999).

The concept of a car-free city is not a city free of motorized vehicles and this vision is agreed on by other authors (Loo, 2018). There are significant advantages related to motorized vehicles such as the movement of heavy goods, aiding immobile people, emergency medical services, and traveling long distances. The key point is effectively eliminating the need for and use of *private* motorized vehicles, especially in cities, which are already hotspots for adverse environmental exposures and health effects related to road transportation (Khreis et al., 2017). To reduce or even eliminate the need for private vehicles in cities, numerous steps are necessary. Most importantly, these steps involve providing and improving alternatives and in the long-term, adjusting city form and land-use to support active travel and (private) car-free living. However, to make such “hard” changes, numerous “soft” processes [see for example (Loo, 2018)] are required as the attitudes, beliefs, and knowledge of decision-makers and the general population have for decades been sold on the advantages of private cars without sufficiently considering its negative implications.

Car-Free Initiatives From Around the World

While there is no agreed-on definition or vision for what a car-free city should look like, examples from around the world give insight into cities’ visions, plans, and already implemented changes. Hamburg, Helsinki, and Oslo have recently announced their plans to become partly private car-free cities (Cathcart-Keays, 2020). Hamburg aims to develop a network of pedestrian and cycling paths to link together different parks and public spaces in the city, while enforcing a car ban on a number of urban roads (Cathcart-Keays, 2020). Helsinki aims to be car-free by 2025, creating a novel mobility-on-demand transportation system, where all shared (including bike and car share) and public transportation options can be utilized through a single payment option using smart-phones (ASLA, 2025), which may render private cars obsolete (Greenfield, 2014). The city’s vision is to make an array of transportation options, beyond the private car, flexible, cheap and well-coordinated, increasing their convenience and ease of use, so that they become competitive with private car ownership (Greenfield, 2014). Some new apartment developments as well, such as the Helsinki’s Kalasatama neighborhood, come with no parking (Peters, 2020). Similarly, Utrecht in the Netherlands is building a new high density, car-free neighborhood for 12,000 people (Boffey, 2020). Oslo made its city center car-free, completely banning some cars on some streets, removing 700 parking spots and replacing them with bike lanes and a different array of green spaces including plants and tiny parks (Peters, 2019). The city is also adding new trams and metro lines with more frequent departures and cheaper tickets (Peters, 2019). Similarly, York in the United Kingdom announced plans to ban most vehicles from its medieval center by 2023, adding an on-demand shuttle service and more bikes to help in the transition (Peters, 2020). Finally, Pontevedra is a small car-free city in Spain. Cars are banned from Pontevedra’s city center, creating a model for a pedestrian-friendly future. In the car-free zone, carbon dioxide (CO₂) emissions have been cut by 70%, nearly three quarters of car journeys were shifted to walking or cycling, and walkers are free to roam (Borgen, 2018).

Other cities have taken less drastic steps, in the same direction, which ban cars on specific days or only ban certain cars which for example do not meet certain emission standards (i.e., more polluting). In a plan known as Madrid Central, Madrid enacted a low-emission zone which bans all petrol vehicles registered before 2000 and all diesel vehicles registered before 2006, unless they meet specific exemptions or are used by residents of the area (Jones, 2018). Brussels, Dublin and London are also discussing banning

diesel vehicles in their city center, while every weekday Milan is offering public transportation tokens to riders who surrender their cars (Cathcart-Keays, 2020). Spearheaded by Mayor Anne Hidalgo, cars are banned from accessing the city center in Paris the first Sunday of every month, increasing access to cyclists, pedestrians and people who use rollerblades and scooters (Coffey, 2020). This ban excludes delivery vehicles, public transportation means and taxis who are still allowed to enter and leave the city center through designated access points and at a maximum speed limit of 20 kilometers per hour (Coffey, 2020). Hidalgo has also been championing the idea of a 15 minutes city, where all Parisians can walk or bike to works and daily errands within 15 minutes (Peters, 2020). Los Angeles adopted the South American-born idea “Ciclovía,” which is a car-free day that closes streets to traffic and sponsors an event to promote active transportation instead. During the program, known as “CicLAVia,” ultrafine particle (UFP) and PM_{2.5} concentrations were measured and found to be reduced by 21% and 49%, respectively, on the streets where cars were banned (Shu et al., 2016). The community wide reductions in PM_{2.5} were less at 12% (Shu et al., 2016). New developments in Utrecht in The Netherlands do not allow residents to own a car but provide neighborhood shared cars for farther trips (Peters, 2020), which is similar to a new development called Culdesac in Tempe, Arizona, which includes basic amenities onsite and is purposefully located near a light rail station that takes commuters to downtown Tempe (Peters, 2020). Car-free developments are becoming more common and can also be seen in England (Morris et al., 2009), and other cities across Europe, most notably including the German neighborhood: Freiburg (Melia, 2006). The district of Vauban in Freiburg, a neighborhood with more than 5000 residents on a former military base, represents that largest car-free development in Europe (Vauban Freiburg Wikipedia, 2020). The tram system in the city provides the backbone for transportation, where 70% of all public transportation trips are made by tram, and 30% are made by bus (Melia, 2006). In this neighborhood, cycling is the predominant mode of transportation where 75% of the working population cycles to work and only 16% of trips are made by car (Melia, 2006). Other cities including Bogota, Brussels, Chengdu, Copenhagen, Hyderabad, Ghent and Rome all have enacted or proposed different measures that aim at reducing car traffic including implementing car-free days, investing in cycling infrastructure and pedestrianization, restricting parking space and considerable increases in public transportation and green space provision (Cathcart-Keays, 2020; Peters, 2020).

Can We Retrofit Cities and Change Mode Share?

Compact cities like Spanish cities may be easier to refit to car-free cities than sprawled cities (Nieuwenhuijsen, 2020). The main challenges will be how to change existing infrastructure that is mainly used by cars to infrastructure for active and public transportation, and how to change people’s perceptions, attitudes, and behaviors and ultimately long-term lifestyles. Some cities have initiated strategies to create car-free spaces like the Superblocks in Barcelona (see below), and these could be transferable to other cities.

A large number of car trips are less than five kilometers (as high as 50%), and those could be replaced by more sustainable and healthier modes of transportation such as cycling (Nieuwenhuijsen, 2020). Cycling has many benefits as it increases physical activity and reduces adverse health outcomes such as premature mortality, it combines transportation with the gym, where on average cyclists weigh two kilograms less than car drivers, it does not cause air and noise pollution, it emits near zero CO₂, it uses much less space than the car, where one car can occupy the same parking space as ten bicycles, and cyclists tend to be happier than other transportation users, with better mental and physical well-being and less stress (Barcelona Institute for Global Health, 2020).

Given the relatively small transportation mode share of cars, Spanish cities (Table 1) are moving toward going car-free, but unfortunately the streets are still dominated by cars. This is partly because even though the mode share is relatively small, there are still hundreds of thousands of cars on the road, and because each car takes up a lot of space. Cities still spend too much money on keeping car drivers happy, and too little on other road and transportation mode users. Therefore, a more concentrated effort is needed to push for a reduction in car use and create car-free streets and neighborhoods in a move towards a car-free city. Also, any new urban development should be car-free and provide good alternatives. Supporting the local economy and creating 15-minute cities with dense and mixed land-use are essential (O’Sullivan, 2020).

Key Reasons for Transitions

The key reasons cited for car-free transitions by cities are to reduce greenhouse gases and mitigate the catastrophic effects of climate change, in addition to reducing air pollution (Nieuwenhuijsen and Khreis, 2016). Indeed, there is evidence that car-free transitions

Table 1 Mode share (%) in Spanish cities (2018)

	Active modes	Public transport	Private transport	Others
Barcelona	46.4	33.3	20.3	0.0
Madrid	40.0	35.0	20.0	5.0
Sevilla	32.3	20.1	43.4	4.2
Bilbao	54.5	22.3	23.2	0.0
Valencia	38.5	22.5	37.3	1.7

Source: Table prepared by Guillem Vich, Barcelona Institute for Global Health

can help achieve these goals. Measurements show that nitrogen dioxide (NO₂) levels, a pollutant which has been associated with many adverse health effects, dropped by 40% during car-free days in Paris (Willsher, 2015), and 20% in Leeds during a quasi-car-free day during the Tour de France (Nieuwenhuijsen and Khreis, 2016). Certain car-free developments cite a wider multitude of reasons including livability, and improved quality of life which is a municipal objective in Freiburg (Melia, 2006). As reviewed in detail elsewhere, the beneficial effects of such transitions would extend well beyond reducing greenhouse gases and air pollution to potentially increasing green space exposures, physical activity, access and social interactions, alongside reducing traffic noise, urban heat, stress and road travel injuries (Nieuwenhuijsen and Khreis, 2016), all associated with improved public health. For example, on Paris's car-free days, measurements show that noise dropped by 50% in the city center (Willsher, 2015). Another health impact assessment exercise modeled the potential environmental and health benefits of the Superblocks model in Barcelona, Spain. While the Superblocks are not exactly a car-free initiative, they do share various elements with the initiatives outlined above including restricting car use in residential blocks to residential traffic only with a maximum speed of 20 kilometers per hour and expanding the active and public transportation network, while increasing the provision of green and open space including plazas, parks, green corridors, green patches and general greening in and outside the Superblocks (Mueller et al., 2019). The health impact assessment estimated that 667 premature deaths could be prevented annually with the implementation of 503 Superblocks covering the city of Barcelona, where the greatest number of avoided deaths is due to reductions in traffic-related NO₂ (291 deaths), followed by noise (163 deaths), heat (117 deaths), green space development (60 deaths), and the increase in physical activity due to the shift from car and motorcycle trips to active and public transportation (36 deaths) (Mueller et al., 2019).

It is important to note that these benefits may be confined to the city centers or areas designated as car-free and that there are valid concerns that car traffic, and the associated adverse exposures, would be displaced to other areas, instead of being eliminated. Examples of this has been shown in the case of air pollution exposure on car-free days in the eastern Po Valley in Italy (Masiol et al., 2014). Research from that region (Masiol et al., 2014) and elsewhere (Burgen, 2018; Mueller et al., 2019) suggests that traffic restrictions should be imposed simultaneously on a larger scale to produce broader benefits to air quality and others, and avoid the exacerbation of environmental injustice, which is tightly linked to transportation planning and policy (Fuller and Brugge, 2020; Mueller et al., 2018). In addition, there are concerns that as the quality of life improves in certain areas where the car-free initiatives take place, gentrification will occur in these areas resulting in rising rents and pushing lower socioeconomic status populations out (known as forced migration) (Mueller et al., 2019). In order to mitigate such risks, traffic restrictions are best implemented city wide with a consistent and equitable distribution.

How to Get There?

While there is no clear consensus or definition of what a car-free city should look like, it seems like a good start for cities is to ban personal car travel within their boundaries, while excluding other essential vehicles like emergency vehicles and also potentially delivery vehicles which meet certain emission standards, keeping in mind that heavy-duty traffic is a key contributor to urban air pollution. The vision for a post-automobile city can go in two directions which are evident in cities' plans from around the world (Bieda, 2016). Cities can completely go car-free, which entails a city model completely devoid of cars. On the other hand, cities can substantially reduce car use, including having designated car-free areas and offering convenient, affordable and competitive alternatives that would ultimately render personal vehicles obsolete. Changes can be incremental, and some cities are already toying with the idea of becoming partly car-free with the implementation of small steps towards that goal including car-free days, low-emission zones, the development of car-free neighborhoods, introducing concepts like the 15-minute city and the Superblocks, as briefly overviewed above. These incremental changes may be a good approach to secure public acceptability as citizens start experiencing the beneficial and pleasant effects of car-free initiatives including improved air quality, reduced noise, and increased physical activity and opportunities for social interactions and cohesion.

To reduce or eliminate the need for personal car travel in cities, many steps need to be taken. Nieuwenhuijsen et al. (2019) suggested nine essential prerequisites underpinning the transition to car-free cities, as illustrated in Fig. 2.

1. Political vision and leadership
2. Mobility to accessibility paradigm shift
3. Alternative convenient and quality transportation means
4. Dedicated funding
5. Media strategy and public involvement and acceptability
6. Intensive data collection and analysis
7. Evaluation of current status, alternative scenarios, and post-evaluation of policies' impacts
8. Stakeholders' involvement and support
9. Detailed plan aligned with other high-level objectives and strategies.

Most importantly, cities need to provide convenient, affordable, and competitive transportation alternatives to the private car such as high-quality public transportation options that are frequent enough, easy to use and affordable, and safe segregated pedestrian and cycling paths, which are well-connected and aesthetically pleasing by for example adding green or blue spaces. Both active and public transportation networks need to be integrated as their integration can potentially allow for the full substitution of car trips by for example covering long distances by public transportation options and short distances such as the

Fig. 2 Prerequisites for car-free cities' implementation. Source: Adapted from [Nieuwenhuijsen et al. \(2019\)](#).

last mile by active transportation options. To be fully functional, the coverage of transportation networks should not only focus on accessing jobs, but also other essential and non-essential destinations including medical care, education, healthy food, shopping, and social networks. The design of these networks should consider climatic factors in the cities where they are implemented. For example, in dry and hot cities, thermal discomfort may hinder the use of active and public transportation, while in humid climates, mechanical discomfort would be an important factor ([Böcker et al., 2016](#); [Shaaban et al., 2018](#); [Miao et al., 2019](#)). Planners and urban designers have options to improve thermal and mechanical discomfort in cities such as creating green and open spaces, including tree canopies, in the vicinity of cycling and pedestrian lanes, designing buildings with moderately nonuniform building heights to improve ventilation, using light colors on walking and cycling paths, and providing shaded paths and public spaces, and shaded or cooled public transportation hubs. Also, importantly, increasing building density and land-use diversity can make active and public transportation more convenient and viable options, and can help reduce exposure to adverse weather by making distances between origins and destinations shorter ([Negev et al., 2020](#)).

These changes are not a function of transportation planning alone but require integration with land-use planning. A paradigm shift from planning for mobility to planning for accessibility in transportation can set new directions in urban development and contribute to the emergence and sustainability of car-free cities. More research and data collection on the impacts of car-free

initiatives is also needed to build the evidence base and the case for such changes, which may be perceived as radical in certain contexts. Such research is currently missing and most of the documentation on city plans for going car-free comes from the gray literature and from Europe and North America, and too often does not include a pre-assessment and post-assessment, which could shed light on how successful these plans are in improving environmental and health conditions.

Citizen and business support for car-free plans is also essential and can be obtained through engaging these groups in the planning dialogue and demonstrating the benefits of such schemes as documented elsewhere or measured in pre- and post-assessments. Specifically, businesses are often opposed to the introduction of car-free zones or initiatives and represent a major barrier to the implementation and sustainability of such plans (Nieuwenhuijsen and Khreis, 2016). For example, car-free restrictions in Oslo have been opposed and hampered by trade associations and shopkeepers, on the basis that such plans may lead to poorer cities with less life and a reduced commercial activity in the city (Cathcart-Keays, 2020). This example from Oslo highlighted the importance of involving stakeholders in car-free transportation planning, including citizens, shopkeepers and trade associations, who in anecdotal evidence seemed happier and more accepting of these plans after their engagement and the revision of some elements to roll out changes in a more incremental manner (Cathcart-Keays, 2020). Similarly, recently in New Orleans, French Quarter residents rallied against proposals to make the historic neighborhood more pedestrian friendly, carrying signs which read as "Save our neighborhood—no pedestrian mall". The residents cited multiple reasons for their opposition including that the proposal will make it harder for them to unload groceries, hamper the work of carpenters who repair and restore historic buildings, and workers who tend bar, tote luggage and work kitchen stoves. Safety concerns were also voiced including that people who work in the French Quarter and get paid tips in cash prefer to get picked up outside work after their shifts, rather than walk with their cash, in an area known for higher rates of crime. Locals also suggested that the proposed plan caters more to tourists than local residents and workers (Reckdahl, 2020). Unfortunately, the car-free literature extent does not specifically covers areas and cities affected by tourism, or engage with issues of gentrification and safety in a comprehensive manner. Other actions which may facilitate the implementation and sustainability of car-free cities and initiatives include the alignment with other policy objectives such as reducing congestion or promoting green growth and the development of a timely media plan to explain the purpose and process of the proposed changes (Nieuwenhuijsen et al., 2019).

While the emergence of car-free cities and the more frequent adaptation of such plans by cities across the world is promising, there is currently no consensus on what these concepts mean or how best they can be implemented including how to overcome a wide range of barriers which are somewhat context specific. This is expected as implementing a car-free scheme in Barcelona will be extremely different from trying to implement one in Houston, as the city was built for cars. Current trends in moving cities' solutions away from the private car and to active and public transportation options signal a change in transportation planning and policy that unfortunately seems to be more restricted to Western Europe, where cities were initially built for walking and horse and carriage and tend to be compact. As European cities experiment with these concepts, it is imperative that research is conducted to measure the impacts of these schemes, not only on environmental exposures and health outcomes, but also on business activity, tourism, safety and economic outcomes. This will help build the case and evidence base for the implementation of car-free cities around the world.

What Holds us Back From Going Car-Free?

Decades of planning and investments in car infrastructure attracted cars to the cities and it will take decades to overturn this. Large car-oriented infrastructures continue to dominate with relatively small proportions of the budget allocated to and little work done for quality active and public transportation provision across most regions. There is an urgent need to rebalance and provide better and safer infrastructures and policy support for active and public transportation modes. For many, the car is still a status symbol and the fastest, easiest and most comfortable way to get around, and negative impacts such as air pollution, noise, heat island effects, and CO₂ emissions are ignored and not communicated well enough. Further, retail interest and car interest groups may be some of the biggest barriers, but their concerns are often unfounded.

A car-free city would provide a catalyst for better town planning by removing the need to facilitate car mobility and ensuring that urban areas are planned around people, functionality, and better built environments instead.

Furthermore, there are many other ongoing changes that may facilitate or hinder the process. Technological advancements such as electric cars and autonomous cars have been proposed as the solution to current issues such as air pollution, greenhouse gases, and road safety, but they have only a limited number of advantages and potentially many disadvantages. The use of electric cars may reduce tailpipe emissions (or at least displace them outside of the city), but it does not reduce non-tailpipe particulate matter emissions (Timmers and Achten, 2016) or the number of cars in the city, and they do not help to reduce other health issues such as deaths and injuries due to crashes, and the lack of daily physical activity. Autonomous vehicles may reduce the number of cars parked in the city, and to some extent the number of cars circulating in the city, but they also have the potential to increase car use in certain population groups, and may increase kilometers traveled as vehicles would need to travel between locations of disparate users, thereby increasing the exposures and health problems related to car use (Rojas-Rueda et al., 2020). If using autonomous vehicles is as easy as waiting for an elevator (an autonomous vertical vehicle) to travel up a few floors, many people will choose to wait rather than making the small effort to actively travel short distances. These technological solutions, which seem to have become a focal point of recent transportation policy, need more investigation and should be integrated within the detailed plans or proposals for future car-free cities. It is not that such technologies won't play a role in future transportation services, but they should not be considered a silver bullet to all current transportation problems.

There are yet many uncertainties in terms of acceptability and behavior change when introducing the car-free city and also the likely changes in terms of air pollution, noise, temperature, social cohesion, and physical activity. There is a research need to evaluate the health impacts of (planned) interventions in cities, including changes in perceptions and attitudes and health impact modeling of future scenarios, in addition to a more meaningful engagement with issues of gentrification, forced migration, the local economy and safety and crime. Further research and research synthesis are needed to build a strong evidence base, which is currently nonexistent. It is also vital to better understand and document how mobility patterns change with the introduction of car-free measures.

Urban Functionality: Model of Mobility and Public Space

Mobility is one of the uses of public space, not the only one. Its purpose is, above all, the functionality of urban systems. Ensuring functionality and, at the same time, the rest of uses in the public space is not simple and is one of the objectives of the superblock concept.

Urban functionality, defined by the mobility and services patterns of each city, determines, largely, the quality and liveability of public space. There is a need to develop a model of mobility and a more sustainable public space, in order to guarantee a more accessible, comfortable, safe, and multifunctional public space where people can be citizens and exercise in the public space the rights to interchange, culture, leisure, expression, and demonstration, besides the right to move. With the current model of mobility, cities dedicate most of the public space to mobility and in these conditions the ultimate aspiration is to be a pedestrian, a mean of transportation. At least 75% of public space should be dedicated to citizen rights. Public space should acquire the maximum liveability but being, at the same time: comfortable (without noise, without air pollution, and with the greatest thermal comfort); attractive (with a high diversity of activities, with attractive activities and with the greatest biodiversity); and ergonomic (accessible, with liberated space to exercise all the rights and with a good relation between built heights and street widths).

A New Urban Cell: The Superblock

The superblock is a cell of nine blocks in the case of the example in Barcelona, defined by a network of basic roads that connects origins and destinations of the whole city (Fig. 1). When the cell is being reproduced along the urban system, the size accommodates the morphological and functional characteristics of the current city (it must be highlighted that the superblocks project is a urban recycling project), liberating the maximum surface of public space, which is nowadays occupied by traffic and, at the same time, guarantee the functionality and organization of the system. The new cell is defined by the perimeter basic roads, where through and connecting traffic circulate at a maximum speed of 50 km/h. Interior roads (intervias) of superblock constitute a local network with limited speed of 10 km/h, speeds which allow shared urban uses. A superblock cannot be crossed, which means that the movements in its interior only make sense if their origin or destination is in the intervias. Therefore, the neighborhood streets will be with little or no noise, or pollution, etc. and allow more than the 70% of space that is currently occupied by the through traffic for the movements by foot or bicycle.

The reasons to choose the dimensions of 3×3 for the superblock are based on the characteristics of cars which, at a speed of 20 km/h (which is the average urban speed in Barcelona), will spend a similar amount of time to go around the superblock as a person walking around the block at about 4 km/h. With the presence of main crossings every 400 m, the traffic lights synchronization is much more efficient (with these distances one can think of prioritization of the traffic lights for public transport) and avoids disruption of the main flux because of turns (two out of three turns are avoided).

Superblock, Base for a Functional and Urbanism Model: The Case of Barcelona

Superblocks aim to be the basis of a functional model of any city, but they can also become the basis of a new urbanism model. The average number of people in a Superblock in Barcelona is higher than 6000 inhabitants. Every superblock emerges as a little city. In this section, we will focus on the superblock as the basis of a new functional model and the consequences for public space.

Road hierarchy in the new Superblock model

CURRENT SITUATION

Basic network: 50 km/h

SOLE RIGHT IN STREET SPACE: MOBILITY
HIGHEST AIM: PEDESTRIAN.

SUPERBLOCK MODEL

Local network: 10 km/h

EXERCISE ALL THE RIGHTS THAT THE CITY OFFERS.
HIGHEST AIM: ACTIVE CITIZEN.

**CIRCULATING
VEHICLES DO
NOT PASS
THROUGH**

Figure 1 Networks scheme, current and future, based on superblocks. Source: BCNecologia

Figure 2 Map of superblocks in Barcelona. Public space (in red) dedicated to mobility. Source: BCNecologia

The defining roads of superblocks (in red) comprise a network of basic roads where the urban transport circulates: collective transport, private vehicle, emergencies, services, and, if the section allows it, bicycles. This network of basic roads, which results in the greatest orthogonality, allows access to the city at the highest speed admitted by law (50 km/h) (Fig. 2).

The basic network of superblocks reduces the length of the total of roads that nowadays is used by through traffic by 61% (see Fig. 2). This dramatic reduction does not lead to a proportional drop-off in the circulation of vehicles for the same level of service (the same speed of the vehicles circulating). In Barcelona, with a reduction of vehicles of about 13% we can achieve a level of service

Figure 3 Public space of Barcelona dedicated to through traffic in the current situation. Source: BCNecologia

similar to current one. It maintains, thus, the functionality and organization of the system. **Fig. 3** shows that the space dedicated nowadays to through traffic is near 15 million of squared meters and the length of the roads dedicated to mobility nearly 912 km, or 85% of the total roads of Barcelona.

The Bus and Bicycle Network

Superblocks allow the integration of networks of through traffic (cars, buses, and bicycles) in its periphery, and priority of movements by foot and bicycle on the inside. Orthogonal networks are the most efficient in urban systems. With the new orthogonal network of buses, the topology of the new network, combined with the distance of the stops every 400 m, contributes to the increase of commercial speed of buses, more so than the traffic lights prioritization or the construction of bus lanes (**Fig. 4**). With the same number of buses that have a frequency of coming every 14–15 min nowadays, there will be a move to a frequency of buses coming around every 5 min in the future (it will be like a surface underground). The service will be the same in the center and in the periphery of the city. The design of the network allows an average waiting time at each stop of around 2 min, which for our mental clock does

Figure 4 Bus network and bicycle network in Barcelona in a superblocks scenario. Source: BCNecologia

not feel like waiting. It is a network that connects any origin with any destination with only one transfer in 95% of cases. It will be an intelligible network like the underground and, the estimated number of transfers will be similar to the underground. In the example fabric, the perpendicularity of the lines of the network allows the presence of a unique stop for the horizontal and vertical lines in all the intersections (in the octagonal crossroads).

The bicycle network will also be adjusted to the superblocks structure (Fig. 4). Superblock's periphery hosts the transport network of bicycles, with exclusive lanes and shares the street section with buses and cars. The interior of the superblocks, at 10 km/h, allows bicycles in both directions, to cross the superblock. Their speed must be adjusted to the speed of pedestrians and the uses that are in place at that moment. If necessary, the rider needs to step off the bicycle. The conditions of intervias allow children go to school by bicycle or by foot without being accompanied by an adult.

The integration of electric engines for the transport is on the agenda of many cities. There is no doubt that the electric bicycle is the electric vehicle to promote. It does not pollute, it does not make noise, it practically does not consume energy (the consumed energy for a journey by electric bicycle, adding the used metabolic energy and the consumed electricity, is less than the energy metabolically consumed doing the same journey by foot); it allows an average person to overcome high slopes of up to 20%, it is healthy, and adjusts the effort to the context. During the summer it even refrigerates—allowing its use in the most severe season without sweating. The homologated motor works up to 25 km/h reducing the severity of accidents. The average distance of the classical bicycle is about 5 km, while electric bicycle increases it up to 10 km, which is the distance from one end to the other in the municipality of Barcelona.

The electric bicycle is, for a distance of 11 km and a speed 30% higher than the speed of a classic bicycle, the most competitive form of mobility.

The isoform distribution of the networks along the city gives a level of service which is equitable for the bus and bicycle networks, something previously only the car had.

The Pedestrian Network

At present, Barcelona has 230 ha of streets with specific space for pedestrians or with speeds limited to 20 km/h. If we add the surface used by the pedestrians in big avenues, the total is about 15.8% of the public space of roads. With the implementation of superblocks 6.22 million of square meters are liberated. This will make it the most important recycling proposal in the world, without demolishing a single building (Fig. 5).

Uses in Public Space and Citizen Rights: From Pedestrians to Citizens

Maybe the most radical aspect of the proposal is the reconversion of most of the urban space to multiple uses and rights. Radical because it goes to the roots of the meaning of public space. A city exists when, first, there is public space and, second, when they are reunited in a limited space by a determined number of legal entities that are complementary and “work” synergistically. We can find ourselves in an urbanization of undetached houses with space for the car to get to the garage. In this case, we talk about urbanized space, but not public space. In urbanization, it makes little sense to have a market, a cultural event, or even, find children playing with balls in the middle of the street.

A city starts to become a city when there is public space, since it is the “house of everybody”, the meeting place for interchange, leisure and staying, culture, expression, and democracy and, also, the movement. Public space makes us citizens and we are so when we have the possibility of occupying it for the exercise of all the rights mentioned above. Today, the limited possibility of exercising the citizen rights relegates us as pedestrians. Giving citizens public space that was lost due to the current model of mobility is key to

Figure 5 Map for pedestrians and other uses. Current scenario and with Superblocks. Source: BCNecologia

the new model of mobility and public space based on superblocks. Electric vehicles can reduce part of the noise (but not the noise that at some speeds comes from the friction between the tires and the bearing surface and not from the engine) and part of the air pollution (as almost half of the pollution caused by particles come from the “dust” lifted by the wheels, that comes from tires particles, brakes, bearing lubricant oils, etc., that, as it is known, contain heavy metals and components of high toxicity). What they cannot reduce is the space that they occupy, which in a compact city in general, and particularly in Barcelona, is the most scarce good.

Superblocks provides citizens with nature in almost 70% of the space of the city. Superblocks allow not only for the integration of transportation networks but also green networks. Furthermore, spaces that are not crossed by any network of mobility: cars, buses, and bicycles. Rights are obtained through speeds that are compatible with the use of the space by the most vulnerable people (for instance, the pass of blind people, children playing). If a Superblock allows a bus network, a car network, or a bicycle network with signalized lane, then it is no longer a Superblock because it is not compatible with all the rights.

The Green Network that Appears with the Implementation of Superblocks

Many urban planners consider that the permeability of the soil a good indicator of naturalization of an urban fabric. The presence of permeable soils rebalances the water cycle: it favors the infiltration of rain waters and retains water through the different vegetable surfaces. The vegetation protects the soil from excessive insulation and protects it from the compaction that provokes the direct impact of raindrops on the soil. By enabling the water to stay longer on surface, it increases the possibility that it infiltrates into the phreatic layers and reduces the risk of floods. It boosts the closing of the cycle of organic matter, by providing the urban soil with surfaces of compost generated by organic waste self-composting. Green spaces and land reservation for urban gardens constitute spaces for generating community among the inhabitants of a neighborhood or territorial unit. Surfaces with vegetable cover help to mitigate the emissions of CO₂, by fixing this gas through the photosynthetic process. Vegetable surfaces are, furthermore, potential captors of polluting particles and help to propitiate thermal comfort, minimizing the heat island effect. Besides, surfaces with trees proportionate acoustic and mechanic comfort, reducing the effect of noise and wind in the urban environment.

There are few areas with permeable soils in Barcelona (Fig. 6). The current green surface in the area of example is only 171.2 ha. The number of square meters per inhabitant is 2.7 m², very far below the 9 m²/inhab the WHO recommends. In a city like Barcelona, with such a lack of free spaces, Superblocks allow us to obtain better values of corrected compactness (balance between urban compression and decompression). The release of only the interiors of blocks in example, is clearly insufficient although necessary. In example, green occupied green spaces. Superblocks will allow us to restore part of the green space that is so needed.

With superblocks, green surfaces increase significantly to 403.7 ha of potential green, while maintaining city's functionality. It will increase from 2.7 m²/inhab to 6.3 m²/inhab for the whole area of Cerdà's Plan. In the Sant Martí area, it increases up to 7.6 m²/inhab. Street transformation and substituting cars with green space, allow us to obtain urban landscapes like the ones that are shown in Fig. 7. It shows the project presented by the City Council to the neighbors of the pilot superblock of Poblenou, for the section of Sancho d'Àvila between Llacuna and Roc Boronat streets (Fig. 8). As Oriol Bohigas said: “A street will have for Latins an infinity of values that a garden won't”. (Bohigas 1958)

A square has been and is the very place for public space. In the case of example of Barcelona, often there are sidewalks of only 5 m of width with little green space. (1.85 m²/inhabitants) With the Superblocks project, the number and surface areas of new squares that are in the junctions of the example fabric will multiply. In a Superblock type of 3 × 3 blocks, four new squares of about 1900 m² will be created (Fig. 8). 130 nodes will become complete squares of 1900 m², adding around 24.7 ha while there will be 20 new squares with a surface of 2/3rd of a complete surface, adding 3 more ha. In total there will be about 150 new squares with a surface of 27.7 ha.

Green from the interiors of block and green covers can also be added. Environmental benefits increase with the increase of urban green surface in height and surface. When you add the public space's green surface and green covers (with an estimated an

occupation of 30%), and the green surface in the interior of blocks (counting 1500 m² per block), green surface per inhabitant increases up to 9.6 m²/inhabitants (Fig. 9).

The Impacts of the Current Mobility Model

Mobility currently brings the biggest dysfunctions to the city. The use of public space is restricted to mobility and Barcelona dedicates more than 60% of public space and 85% of roads to traffic.

Figure 10 Morbidity in Barcelona by different reasons. Source: ISGlobal

Air pollution emitted by motorized traffic has an unacceptable impact on the health of population in the Metropolitan Area of Barcelona. In a study conducted by ISGlobal CREAL in an area of 56 municipalities, including Barcelona, it was estimated that air pollution causes: 3500 premature deaths per year; 1800 hospitalizations by cardiovascular reasons; 5100 cases of chronic bronchitis in adults; 31,100 cases of children bronchitis; 54,000 asthma attacks among children and adults. (Künzli and Pérez, 2007).

The impacts of air pollution on health are today the main problem to solve out of all the problems caused by the current model of mobility. The liveability index in most of the city is below minimal. The green surface in central example is 1.85 m² per inhabitant when the WHO recommends 9 m²/inhab. Example is also the district with the most traffic; almost 50% of the population is exposed to inadmissible levels of noise (diurnal values >65 dbA). The negative economic impact runs in the millions of Euros per year (according to the World Bank, for Spain it was 45,000 million of Euros/year in 2013, considering only the impact on the health). Black asphalt and the emissions of cars are responsible for the most important part of the urban heat island. This increase of more than 2° of average temperature (at summer nights can surpass the 5° of difference compared to periphery) is especially painful and in some cases mortal, for the most vulnerable people: elderly, children and sick people, particularly when the heat waves occur because of [climate change](#). Traffic accidents caused 30 deaths per year in Barcelona and more than 30 injuries per km/year in example. Visual intrusion and landscape deterioration (landscape as expression of the integration of different variables) convert Barcelona in a “pressure cooker” affecting 85% of the length of streets in the city.

The results of a study conducted by ISGlobal (Mueller et al., 2017) for Barcelona and its Metropolitan Area, show clearly the impact that some of the exposures have on morbidity of the citizens of Barcelona (Fig. 10).

The second (Mueller et al., 2019) calculates the number of premature deaths (and the causes) that could be avoided with the implantation of the superblocks in Barcelona (Fig. 11).

Figure 11 Annual premature deaths that the “superblocks” model could avoid in Barcelona. Source: ISGlobal

Figure 12 Air quality and urban noise in Barcelona. Exposed population (in %) to levels of NO_2 and decibels legally admissible. Current scenario and with superblocks. Source: BCNecologia

The result is a city that is not ready to address the great challenges of the beginning of century: sustainability in the information age. There is need for a new ecosystemic model with its corresponding system of proportions that includes, at the same time, the reduction of: polluting emissions, noise, energy and the increase of: green, staying spaces; legal entities diversity, also the one dense in knowledge. An urban model that extends along the city and takes into account the current modes of mobility. To address these serious problems, the Sustainable Urban Mobility Plan of Barcelona approved by the City Council (March 2015) proposes to extend the Superblocks throughout the city and reduce 21% of circulating vehicles. With this reduction it is estimated that the levels of air pollution in all the measurement stations will be below the guideline values. With a reduction of 21% of circulating vehicles, the level of service of traffic and the environmental conditions of roads in a superblocks scenario will be much better than now.

With this reduction of vehicles, the percentage of people exposed to levels below the guidelines for air pollution will be 94% (today it is 56%) and for noise 73.5% (nowadays it is 54%). The liveability index will increase significantly in all the neighborhoods of the city (Fig. 12).

Superblocks, a Tool That Helps to Mitigation and Adaptation to Climate Change (Climate Change Assessment)

Urban heat islands form due to the emissions of heat by part of the series of surfaces that configure physical parts of the city. The emission of heat to the atmosphere is a consequence of different factors, like for example: climate conditions of the place, urban morphology, distribution of materials of the different urban surfaces, (pavements, covers and façades) and also by the heat produced by the activity of the city (traffic, building's conditioning, etc.) (Martín-Vide, 2015).

Currently, cities are characterized by the predominance of impermeable surfaces. This aspect produces an important concentration of heat, especially in the asphalt pavements of urban roads and the buildings. One of the areas of discussion of climate change is precisely the mitigation of urban heat island because its impact has repercussions both for energy consumption and people's well-being, reducing the comfort levels during the day and above all during night. Heat absorbed during the day is freed during night, increasing notably the temperatures of summer nights. That is why it is important to implement measures that allow mitigating urban heat generation and reducing urban centers temperature.

Figure 13 Thermal simulation comparing example in current situation and with superblocks. Source: BCNecologia

To reduce the current heat island effects, it is necessary to reduce the number of vehicles circulating and the consumption of fossil fuel energy, as well as to extend a green carpet that allows us to increase our resilience toward heat waves that will become more frequent with climate change. Superblocks will help in the mitigation and in the adaptation of the problem.

Through simulations of heat transfer for a summer day in Barcelona, one can demonstrate the repercussion of the current urban morphology and with Superblocks. The Superblock scenario will substitute the asphalted pavements in intervias with semipermeable pavements and the greatest cover of road trees. It will dedicate 30% of cover surfaces to green covers and release 1500 m² of interior patios of each of the blocks to green spaces. This has been analyzed in two areas of Superblocks in the left part of example (Fig. 13).

Results clearly indicate how the current situation of urban fabric in example is warmer than the Superblocks proposal. In terms of heat balance,¹ while the current fabric is 72.1 kW/m², the superblocks proposal obtains a balance of 46.3 kW/m², 35.9% less than the current situation. This energy translates into lower surface temperatures of pavements, buildings, and green spaces.

The heat balance by radiation refers to the sum of heat gained by radiation both in short and long wavelength. In incident solar radiation (short wave) a part is absorbed, and another proportion is reflected according to material's albedo.

Absorbed radiation accorded to the thermal capacity and emissivity of materials is equally emitted as long wave to the rest of materials. From the albedo characteristics and emissivity of materials in pavements, façades and covers, it is calculated the total of heat produced during the day in energy units of kW/m².

Introduction

Our daily lives as well as society at large have become increasingly dependent on critical infrastructure systems providing amenities, such as electric power supply, information and telecommunications (ICT), and not least, mobility and freight transport. Over time, the systems have become more complex and intertwined, with consequences of disruptions that are difficult to identify, understand, and mitigate. Because they are critical to society, their *resilience*, that is, ability to resist, absorb, adapt, and quickly recover from shocks, disruptions, and deliberate attacks, has become an important societal goal.

The transport system can conceptually be divided into three parts (**Fig. 1**):

1. technical and physical infrastructure including rails, roads, terminals, airports, ports, vehicles, signals, signs, etc.
2. direct and indirect users of the technology, that is, travelers, transporters, and society in general,
3. actors responsible for planning, operating and maintaining the infrastructure, and services under given regulations and budget restrictions.

Shocks to the transport system can initiate in any of the three parts and then propagate to the other parts. Infrastructure disruptions are caused by, for example, technical failures (bridge collapses, power outages, vehicle malfunctions, etc.), extreme operating conditions (floods, snow storms, etc.), or deliberate attacks. User disruptions can occur due to economic crises, conflicts, and health crises, such as the Covid-19 pandemic. Disruptions in the management may arise from, for example, political shifts or labor conflicts. Climate change will be an increasing threat primarily to the transport infrastructure. Ironically, the transport system has contributed to this threat through its hitherto almost total dependence on fossil fuels.

Societal shocks can be completely unexpected. While the risk of a pandemic was known, Covid-19 had cascading effects on the economy and the transport system to an extent never seen before. The surprisingly rapid global spread of Covid-19 is, in part, explained by the extreme level of mobility offered by today's transport system ([Musselwhite et al., 2020](#); [Peeri et al., 2020](#)). Most countries sought to suppress the spread by closing borders and restricting mobility locally and globally as well as locking down activities and businesses. This led to a drastic reduction in travel demand, followed by a corresponding reduction in supply. The effects were most pronounced for the aviation industry. Public transport, including rail, was also greatly affected. However, the transport infrastructure was left intact.

Resilience and Related Concepts

[Holling \(1973\)](#) introduced resilience as a term for an ecological system's ability to absorb changes and shocks and still persist. Another ecologist, [Pimm \(1984\)](#), defined resilience as the rapidity with which a system returns to equilibrium after a perturbation. Both these views are typically included in recent definitions of the resilience of transport systems. [Rose \(2007\)](#), for instance, expresses this as a distinction between *static resilience*, a system's capability to maintain its function, and *dynamic resilience*, the rate at which a system returns to equilibrium after a disturbance. [Bruneau et al. \(2003\)](#) understand a resilient system as one that has reduced the probabilities of shocks, that exposed to a shock experiences moderate consequences, and that recovers quickly. A large number of similar definitions have been suggested. We summarize them as follows (inspired in particular by [UNISDR, 2009](#)):

Figure 1 A trisecting model of the transport system.

Figure 2 Stylized illustration of resilience and vulnerability of transport systems. Source: Adapted from Bruneau et al., (2003); McDaniel et al., (2008).

Definition

Resilience is the ability of a transport system to prepare for and to withstand, absorb and adapt to shocks, and to recover from the consequences in a timely and efficient manner.

Bruneau et al. (2003) specify four properties that characterize a resilient system: *robustness*, *redundancy*, *resourcefulness*, and *rapidity*. Robustness reflects the ability to withstand shocks without or with only limited degradation of service. Redundancy reflects the extent to which there are alternative units that can function as substitutes and hence absorb the consequences of degradation. Resourcefulness reflects the capacity to identify problems, prioritize actions, and mobilize necessary material and human resources to adapt and recover the system. Rapidity reflects the capacity to recover in a timely and efficient manner. The robustness and redundancy represent the static aspect of resilience, whereas resourcefulness and rapidity represent the dynamic aspect.

The relation between different concepts is illustrated in Fig. 2. The area between the straight horizontal line and the curved line below represents the total loss of function, that is, lack of resilience against a specific shock (Bruneau et al., 2003). (The lack of resilience R can be represented quantitatively as $R = \int_{t_0}^{t_1} [Q_0 - Q(t)] dt$, where Q_0 is the normal and $Q(t)$ the time-varying quality of service (system function) between the time t_0 , when the shock occurs, and the time t_1 , when the function is restored to its pre-shock level). This lack is obviously dependent on ex ante mitigation measures and ex-post adaptation measures that have been taken. The figure does not represent the extent to which the likelihood of shocks has been reduced but presents the situation conditional on that a shock has occurred. This may be termed *conditional resilience*.

There are many related concepts, in particular *risk* and *vulnerability*. Following Kaplan and Garrick (1981), *risk* can be defined as a set of triplets, each one consisting of a scenario, the probability, and the consequence in terms of damage resulting from the scenario. (Formally they define $\text{risk} = \{ \langle \text{scenario}_i, \text{probability}_i, \text{consequence}_i \rangle \mid i = 1, 2, \dots, I \}$). The scenario is a description of a chain of (unwanted, negative) events that can happen. The consequence corresponds to conditional lack of resilience. Measures taken by the system owner to strengthen the system become part of risk management.

Vulnerability of a transport system may be defined as a susceptibility to events that can result in considerable reductions in transport system serviceability (Berdica, 2002) or, with a shorter but similar formulation, as society's risk of transport system disruptions and degradation (Jenelius and Mattsson, 2015). Vulnerability studies aim at finding the weaknesses in a system, estimating the probabilities that they will lead to serious deterioration and the consequences thereof. The term vulnerability is

Table 1 Causes of disruptions in transport infrastructure.

Where Origin	Natural	Human-made unintentional	Human-made intentional
Inside	Technical failure	Accident, handling error, negligence	Malicious insider, labor market dispute
Outside	Natural disaster, earthquake, extreme weather, technical failure	Accident, handling error, negligence	Act of war, terrorist attack, criminal action, prank

Table 2 Examples of weather-related transport system disruptions

Weather condition	Transport mode	Possible infrastructure impacts	Possible effects on users
Heavy snowfall	Road	Drainage blocking, road and bridge destruction, road blocking	Slow driving speed, reduced accessibility, cancelled trips
	Rail	Track damage and blocking, electricity loss, freezing of switches	Stopped and cancelled trains, lower speeds, accidents
	Air	Blocked runways	Delays, cancelled flights
Heavy rain	Road	Drainage blocking, road and bridge destruction, road flooding	Slow driving speed, reduced accessibility, cancelled trips
	Rail	Track damage and blocking	Stopped and cancelled trains, lower speeds, accidents
Drought	Air	Blocked routes, closed airports	Delays, cancelled, and diverted flights
	Road	Forest fires, road damage and blocking	Reduced accessibility, cancelled trips
	Rail	Forest fires, track damage and blocking, electricity loss	Stopped and cancelled trains
	Waterway (inland)	Lower water levels	Slow speed, reduced carrying capacity, reduced accessibility
Heavy wind	Waterway	Ship and port damage, stopped or cancelled ferries	Delays, accidents
	Air	Reduced ground, take-off and landing speed, turbulence	Delays, accidents, discomfort
Sandstorm, volcanic ash	Air	Airspace closed, engine damage	Delays, cancelled, and diverted flights

Source: Adapted from Leviäkangas et al., 2011

often used even if there is no attempt to determine the probability of disruption. When a distinction is necessary, this may be termed conditional vulnerability. A vulnerability study can help the system manager identify the critical elements of a system and which preventive measures that would be most valuable. Vulnerability as opposed to resilience studies are thus more limited and are primarily focused on how the robustness of a system can be strengthened. In Fig. 2, conditional vulnerability corresponds to how much the system function will decrease when subject to a shock, or the normal level of function minus the robustness. (Formally, conditional vulnerability is $Q_0 - \min_{t \in [t_0, t_1]} Q(t)$).

Causes and Consequences of Disruptions

Disruptions in transport systems can take many forms (see Table 1). It is useful to distinguish between disruptions caused by “nature,” technical failures and unintentional errors on the one hand, and disruptions caused by malign individuals on the other hand. In the first case, there is a certain element of randomness as to when and where disruptions occur. Internal threats in the form of technical failures, accidents, and handling errors fall within the domain of system managers with more direct control compared to external causes. In some cases, a combination of both technical and human factors contributes to initiate and exacerbate an incident.

The transport system is also heavily exposed to external threats such as disasters, extreme weather, and technical failures in other infrastructure. The unexpectedness of many of these threats makes it difficult to protect the transport system. Table 2 lists a few examples of weather-related transport system disruptions. As climate change continues, extreme weather can be expected to become more common and its effects on transport more severe (Koetsee and Rietveld, 2009).

External threats also include deliberate attacks such as sabotage, terrorism, and acts of war. Tragically, almost all modes of transport have been subject to deadly terrorist attacks. An intelligent adversary can be expected to look for vulnerabilities in a system and where and when it is poorly protected. A malicious insider can be particularly well-informed about a system’s vulnerabilities. Since the transport system is critical for companies and people, it is also often exposed to labor market conflicts, not least in labor-intensive modes such as air, rail, and public transport. Table 3 lists some notable historical disruptive events and Figs. 3–6 show some of the sites where they occurred.

Different transport subsystems, or modes, have different resilience characteristics. The road transport system provides the majority of all inland passenger and ton kilometers transported. Road transport is characterized by relatively high levels of

Table 3 Examples of transport system disruptions.

Transport mode	Location, date	Initiating event	Transport system damage
Waterway (maritime)	Baltic Sea, 1994	Rough weather, damaged bow visor	Passenger ferry sank, 852 died from drowning and hypothermia
Rail	Madrid, 2004	Terrorist bomb	Train cars exploded, 193 died, some 2,000 injured
Air	Iceland, 2010	Volcanic ash cloud	European airspace closed for more than a week
All	Chile, 2010	Earthquake followed by tsunami	All transport infrastructure seriously damaged, officially 525 died, 25 missing
Public transport and other modes	New York, 2012	Hurricane Sandy	Flooding, subway and other traffic stopped for 5 days or more
Road	Genoa, 2018	Rain, technical failure under investigation	Collapsed bridge, 43 died and 16 injured

independence for the users and redundancy in routes. This implies that the users are well-equipped to handle disruptions through detours and rescheduling. Remote areas may be vulnerable to disruptions at a particular critical location, for example, a bridge, while urban areas can suffer from cascading congestion and queues. Even in dense networks, area-covering disruptions such as floods can have severe consequences (Jenelius and Mattsson, 2015).

Compared to roads, rail traffic is characterized by substantially more regulation and control. The system is dependent on other critical infrastructure, in particular the electric power grid. The dependence on labor, ICT systems as well as mechanical and electric systems is also high. Route redundancy is typically low, and overtaking stopped trains is difficult, if not impossible. These factors contribute to make the rail system relatively sensitive to disruptions.

Figure 5 The collapsed Morandi Bridge in Genoa, Italy, 2018. Source: Salvatore Fabrizio, CC BY 4.0, Available from: <https://commons.wikimedia.org/w/index.php?curid=71622568>.

Air traffic is characterized by high safety and security concerns coupled with private market competition and strong dependencies on labor, fuel supply, ICT, and electric systems. The network consists of nodes (airports) with strict regulations and interdependencies between vehicles and journeys, and links (flights) with high degrees of freedom concerning flight path and speed. Disturbances that tend to originate at nodes can lead to knock-on delays and missed connections.

Public transport can offer efficient mobility in urban areas as well as base levels of accessibility in remote areas, and can be provided in the road, rail, waterway, and even air transport systems. Depending on the transport mode, public transport is thus subject to the vulnerabilities of each system discussed earlier. The system is further characterized by the schedule-based operations, and traffic disturbances may lead to long in-vehicle travel times, waiting times, crowding, and denied boarding.

Consequences of disruptions range from annoying delays, missed travel connections, interrupted trips, and delayed goods deliveries, to economic decline due to reduced transport opportunities and, not least, injuries and deaths due to accidents, disasters, or deliberate attacks. It is challenging to evaluate these very different dimensions in a one-dimensional consequence indicator. Cost-benefit analysis of transport policy measures may possibly serve as an example. The effects on accidents, the environment, accessibility, and wider economic benefits are then summarized in a monetary value according to a well-defined procedure. However, shocks have impacts in dimensions not typically included in traditional cost-benefit analysis. Taking Covid-19 as an example, although the consequences for the transport system were very significant, the major consequences were in terms of people's life, health, and the economy. Exceptional events may also affect citizens' perceived security and their confidence in the public institutions' ability to protect them. Such effects are difficult to value in monetary terms. Since different social strata and geographical areas are affected unevenly by a disruption, fairness aspects must also be taken into account.

Tools to Study Resilience

Data on past disruptions can provide valuable information to better prepare for future threats. This is especially relevant for natural and unintentional manmade disruptions. For intentional attacks, historical data has less relevance for where and when future attacks may occur, as an adversary likely wants to surprise a defender.

It is intuitive to conceptualize transport infrastructure as a network or graph, comprising a set of nodes (or vertices), and a set of links (or edges) in which each link connects two nodes. The appropriate network representation of the system depends on the scope

of the analysis. A common representation of the air transport system, for example, is to model airports as nodes and connections or specific flights as links. The basic node and link structure is known as the topology of the network. On top of the topology can be added other properties such as link weights (for example, lengths, travel times or costs) and capacity constraints. The most sophisticated network models involve detailed dynamic, sometimes stochastic, simulation of the interactions between vehicles and the stationary infrastructure (Bell and Iida, 1997; de Dios Ortúzar and Willumsen, 2011).

A network model can be used to analyze the resilience against disruptions represented as failures/removals of nodes or links. A simple measure of network connectivity is the relative size of the largest connected component of the network, that is, the largest number of nodes that can be reached from each other through at least one network route. Another measure is the average distance between all node pairs, where distance is defined as the length of the shortest path connecting each node pair. If the network is not connected, which may happen after link and node removals, the average distance becomes infinite. Latora and Marchiori (2001) introduce an efficiency indicator defined as the average across all node pairs of the reciprocals of the node pair distances. (In mathematical terms, the efficiency metric is defined as $E = \frac{1}{N(N-1)} \sum_{i \neq j \in V} \frac{1}{d_{ij}}$, where V is the node set, N is the number of nodes, and d_{ij} is the network distance between nodes i and j .) This indicator is well-defined also for nonconnected networks, and the change in efficiency can be used as a vulnerability metric. (Formally, the (conditional) vulnerability to a removal of node i can be defined as $E_0 - E_i$, where E_0 is the efficiency of the nominal network and E_i is the efficiency with node i removed).

There is an important connection between the resilience and vulnerability of a transport network and its topological structure, in particular the existence and location of central nodes and links (Reggiani, 2013; Zhang et al., 2015). A simple local measure of node centrality is the *degree*, that is, the number of links connecting directly to the node. In the air transport network example, the degree of a node is the number of routes or flights connecting an airport to other airports. High-degree nodes are sometimes known as hubs. The distribution of degrees among network nodes has attracted considerable interest. The network is said to be scale-free if the degree distribution follows a power law, at least asymptotically, that is, decreases as $k^{-\gamma}$ for large values of the degree k . The exponent γ is typically between 2 and 3. Scale-free networks are considered robust to random failures but vulnerable to successful attacks on high-degree nodes (Lin and Ban, 2013). A global measure of node centrality is *betweenness*, which is the number of shortest paths between all other node pairs that include the node. In the air transport network, high betweenness indicates that the airport is an important transfer location. Degree and betweenness are illustrated in Fig. 7.

The network-modeling paradigm can be extended to include the transport users, in particular travelers and goods. These can be modeled as travel demand between special source (origin) and sink (destination) nodes, which enters the network as link flows. More elaborate network models may incorporate congestion (flow-dependent link costs), demand routing mechanisms, dynamic and stochastic demand, etc. Including transport demand in the network model allows for more nuanced metrics of resilience against node and link removals. A useful measure is the *unsatisfied demand*, defined as the amount of flow, which is unable to reach its destinations. If each link is associated with a travel time (or cost), a meaningful resilience metric is the increase in total travel time (or cost) (Jenelius and Mattsson, 2015). Figure 8 illustrates the potential impacts of link removals.

Figure 7 Nodes of high degree (left) and betweenness (right) centrality

Figure 8 Left: Undamaged network, shortest path flow from source: A to sink B. Middle: Rerouting due to link removal, increased shortest path length. Right: Network fragmentation due to link removal, unsatisfied demand.

At the finest level of detail, agent-based models can represent each traveler and vehicle as an individual object with unique properties. Such frameworks can be used to capture the dynamic dimension of resilience, including the deterioration and eventual restoration of system function associated with a disruption (Malandri et al., 2018).

Different types of disruptive events require different modeling approaches. Disruptions caused by “nature” or unintentional human actions are often appropriately modeled as removals of randomly selected nodes or links. Random removals of multiple links or nodes can be studied as well but increases the combinatorial complexity.

Disruptions caused by intentional human interventions are likely targeted towards network components where they can achieve as much damage as possible. Data on past attacks will then say little about future attacks. It may be better to analyze who may be interested in and capable of performing such an attack. A commonly studied strategy is to attack the nodes with the highest degree, thereby disrupting as many local connections as possible. Another strategy is to target the global connectivity by attacking the nodes with the highest betweenness centrality or transport flow. Some studies evaluate resilience in terms of how network function deteriorates as increasing numbers of nodes are removed (for example, Zhang et al., 2016).

A characteristic feature of intentional attacks is that the strategy for targeting network components can adapt to measures taken by society to protect the system. Thus, protecting the most vulnerable components from attacks could divert attacks to other, less protected components. Here, *game theory* can provide insights into the risk for attacks across the transport. For example, consider a situation when an antagonist wants to disrupt freight transport by attacking a network link, while the transporter wants to route the freight to minimize the expected losses. In this case, optimal strategies for the transporter can be found by studying the *Nash equilibria* of the conflict, that is, strategy combinations under which no actor can single-handedly increase its payoff by changing strategy (Bell et al., 2008).

Enhancing Resilience

Since resilience is a multifaceted concept, a set of proactive and reactive measures is required to enhance it. To some extent, potential threats may be avoided. For actions such as investments in new railways, roads, and other physical infrastructure, national transport authorities have the capacity to make the decisions. To some extent, they can avoid sites that are exposed to natural threats like floods, landslides, and adverse weather. However, trying to protect the transport system from any conceivable threat or disruption would be prohibitively expensive. The most challenging example is climate change. If effective measures to stop or at least limit climate change are implemented, the expected increase in extreme weather can be reduced. To realize such a policy, decisions outside the transport system at an international political level are necessary.

For shocks like earthquakes, tsunamis, and deliberate attacks, it is impossible to predict with accuracy where and when they will occur. Other shocks are hardly possible to imagine in advance. This was the case with the transport impacts of Covid-19 through the measures taken to limit its spread. Therefore, reactive measures to withstand, absorb, and adapt to shocks are also necessary. The properties that characterize a resilient system, robustness, redundancy, resourcefulness, and rapidity, are helpful in structuring such considerations (Bruneau et al., 2003).

Robustness and redundancy are primarily associated with the static aspect of resilience. A robust transport system can withstand shocks with no or limited degradation of service. Roads, bridges, railways, drainage, and other critical technical elements can be built to withstand and absorb considerable external stress and planned to be regularly inspected, repaired and maintained. The most obvious example of increasing the resilience of a transport network through redundancy is to add links to increase the number of alternative routes. Different transport modes can partly substitute for each other. Reserve capacity for personnel and vehicles in, for example, public transport, can help coping with increased sick leave or sudden technical problems. The tools discussed in the previous section are valuable for identifying the elements in the transport networks that are most critical to strengthen and maintain, and the degree to which increased redundancy can absorb the consequences of degradations. Table 4 provides examples of policy instruments to enhance resilience against flooding in an Indian context.

Resourcefulness and rapidity are primarily associated with the dynamic aspect of resilience, that is, reducing the total consequences through timely mitigation and restoration. Resourcefulness reflects the ability to identify problems, prioritize actions, and mobilize necessary material and human resources to adapt and recover the system. The capacity to handle disruptions can be strengthened through a high level of readiness, including relevant equipment and personnel who are well-trained in handling the

Table 4 Examples of actions to enhance resilience against flooding

Phase	Mechanism	Action	Effect on transport
Proactive	Avoidance	Restricting development in low lying or vulnerable areas Slum relocation and rehabilitation	Fewer travelers exposed to flooding Fewer travelers exposed to flooding
	Robustness	Providing proper drainage facilities at vulnerable areas Replacement of impermeable road surface with permeable material in vulnerable areas	Decreased road inundation Decreased road inundation
	Redundancy	Construction of redundant infrastructure	More route options
Reactive	Adaptation	Rerouting people during flooding	Travelers less affected by flooding

Table 5 Examples of recommended preventive actions to enhance resilience to extreme weather events*Preventive actions to enhance resilience to extreme weather events*

Consider whether there are potential “single points of failure” in the networks, which leave parts of the country at risk of having vital economic and social links severed. Identify a “critical network,” comprising those routes which are of national economic significance and should be maintained to a higher level.

All transport operators should have contingency plans to cope with extreme weather events.

Contingency plans should be regularly rehearsed and progressively extended.

All transport operators should ensure they have clearly agreed channels for receiving weather and flood forecasts.

All transport operators and authorities should implement a dedicated passenger and user communications plan for times of transport disruption.

In the face of an extreme weather event, transport operators should plan for the best practicable service which they can realistically deliver.

Transport operators should have checklists of resources which they will need as part of their recovery effort.

Rail infrastructure operator should liaise with its electricity suppliers to trace through the routes and sub-stations to ensure adequate system redundancy.

Contingency rail timetables should be prepared to match different weather events.

Rail infrastructure operator should have adequate resources available for clearing fallen trees.

equipment and dealing with accidents and disasters. Adequate information systems to alarm rescue forces about disruptions and help them coordinate relief efforts are important. In addition, resources must be available to reduce the consequences for those directly or indirectly affected by a disruption. Travelers often have to wait for hours at airports, on stopped trains or in car queues. Such consequences can be partially mitigated by providing travelers with relevant information to facilitate their own decisions. To ensure that the transport system is well prepared to minimize the consequences of disruptions, a number of measures must be implemented. **Table 5** gives some examples from the United Kingdom of recommended preventive measures to improve the transport system’s resilience to extreme weather.

Ongoing Trends

Continued technological development can be expected to make infrastructure systems increasingly intertwined. Among the transport subsystems, the road system has been the least dependent on other infrastructure systems. The development of connected autonomous vehicles may change this through the need for wireless communication with other vehicles, infrastructure and global satellite navigation systems. Moreover, if a vehicle loses contact with the support systems, it must be able to stop safely. Mobility-as-a-service is a new concept that requires reliable wireless communication for ordering and operating the vehicles. Since the communication is vulnerable to intentional and unintentional disturbances, it is necessary to make the channels reliable and secure. Another important trend affecting particularly the road transport system is the electrification of vehicles, which increases the dependence on the electric power system. A resilient road transport system with self-driving electrified vehicles requires both interference-free wireless communication and reliable electricity supply.

Climate change has far-reaching consequences for transport. Extreme weather such as hurricanes, heavy rain, and drought are forecasted to become more common. This will lead to a higher frequency of disruptions in the transport networks due to, for example, storm-felled trees, landslides, floods, and forest fires. Further, policies aimed at reducing carbon emissions and reaching the Agenda 2030 sustainable development goals will by necessity create significant shocks to transport users through changes in vehicle technologies, regulations, taxes, fuel prices, ticket and shipping prices, etc.

The impact of the Covid-19 pandemic on mobility and demand for transport has been profound. To stop the spread of the virus, authorities locked down many activities and drastically restricted physical contacts and mobility. The responses to these actions illustrate the flexibility and adaptability that exists in society. The biggest adjustment made by individuals in both private and working life is arguably the change from physical to virtual contacts. Since this requires access and familiarity with, for example, video conferencing systems, it is reasonable to assume that many will continue to meet virtually also after Covid-19 once this effort has been made. Whether it will reduce travel in the long run remains to be seen. Covid-19’s stimulus of e-commerce is another effect that can be lasting. In the aviation sector, demand fell to almost zero and many companies have gone bankrupt or needed great financial support from governments to survive. When air traffic resumes to a fairly normal level, ticket prices and freight rates are likely to be higher than before the pandemic. Combined with the debate on the climate effects of aviation, this may lead to a significant, lasting reduction in air traffic. The increased familiarity with video conferences may further contribute to this. The impacts on transport resilience of these potential mobility effects are difficult to speculate about. However, what we have learned from Covid-19 is that human adaptability and ingenuity are very large when sudden changes occur. This is an unplanned and unexpected form of resilience.

Concluding Remarks

By resilience is meant a transport system’s ability to prepare for and to withstand, absorb and adapt to shocks, and to recover from the consequences in a timely and efficient manner. The significance of transport systems makes their resilience an important policy

issue. Transport also has a key role for other infrastructure systems in facilitating rescue and repair personnel to quickly get in place to handle the consequences after a disruption. The severity of shocks to the transport systems can vary widely, as well as the causes. Different transport systems exhibit different characteristics from a resilience perspective, depending, for example, on how the behavior of the users is regulated. In the road system, users can often make detours to avoid disrupted links. The rail system is substantially more regulated and rerouting is decided at the level of traffic control.

Research on resilience, risk and vulnerability of transport systems has exploded the last two decades. Tools to study resilience have been developed that can help identifying vulnerabilities in the systems. The tools are also helpful in evaluating measures to enhance resilience. Hopefully, the implementation of new research findings will help decision-makers to make the transport systems less vulnerable and more resilient.

Biographies

Erik Jenelius holds an MSc degree in engineering physics and a PhD degree in infrastructure from KTH Royal Institute of Technology, Stockholm, Sweden. He is an Associate Professor in Public Transport Systems and Head of the Division of Transport Planning at the same university. His research interests include data-driven traffic management, sustainable urban mobility, transport network and resilience analysis, and public transport systems planning and operations.

Lars-Göran Mattsson holds an MSc degree in engineering physics and a PhD degree in optimization from KTH Royal Institute of Technology, Stockholm, Sweden. He is a Professor Emeritus in Transport Systems Analysis at the same university. His main research interest is systems analysis for the public sector. In addition to transport research, this includes research in urban and regional planning, health care, and economics. A particular area of research is risk, vulnerability, and resilience of critical infrastructure.

Introduction

Shipping is a growing transportation sector due to its reliability, affordability and global nature. Vessels getting bigger (i.e., tankers, bulk carriers, and container ships), faster and more efficient can carry billions of tons of goods along a few principal trade routes of the global trade, being shipping the most efficient mode of transportation. For example, in one year, a single large containership could carry over 200,000 container loads of cargo (<http://www.worldshipping.org/>). World seaborne trade volumes are estimated at about 80% of the global goods trade (UNCTAD, 2016). In Europe, currently almost 90% of the European Union (thereafter EU) import and export freight trade is seaborne (Karl et al., 2019), with a total of 2.1 million vessels calling in main European harbors in 2016 (EUROSTAT, 2019). Tourist shipping is also increasing in terms of passengers and size of cruise ships are continuously increasing (Contini et al., 2015), with a total of 397 million passengers in EU harbors in 2016, and a rise of 0.4% compared to the previous year (EUROSTAT, 2019).

Apart from economic growth and energy efficiency of ships, the environmental issues are needed to be investigated at different levels. It is important to discriminate between local impacts (near harbor areas) and open-sea traffic influence at continental and global scale. At local scale, harbor development could lead to a conflict of interest between stakeholders and local population (most of the harbors and terminals are located close to the urban areas), however, harbors are committed to being “green” while building prosperity for present and future generations in a mutual concept of “sustainability” and “economic and social scope.” In this perspective, because of the pressure on the environment and potential health effects, air quality was underlined as the main and fundamental goal within harbor management.

Shipping emissions predominantly consist in primary and secondary particulate matter (PM, mainly particles of small size), black carbon (BC), sulfur dioxide (SO₂), nitrogen oxides (NO_x), volatile organic compounds (VOCs), carbon oxide (CO), and carbon dioxide (CO₂). Trace elements like metals in PM (e.g., Vanadium - V - and Nickel - Ni - that are considered tracer of this emission) and PAHs (polycyclic aromatic hydrocarbons), in gas and particulate phases) are also important compounds released by ships. Further, taking into account that, for decades, heavy fuel oil (HFO) has been the cheapest, most efficient but also the most polluting fuel, ocean vessels powered by HFO have emitted greenhouse gases (GHGs). These pollutants are known to deteriorate air quality producing adverse health effects (Corbett et al., 2007; Oeder et al., 2015; Liu et al., 2016) and negative effects on climate (Fuglestedt et al., 2009; Eyring et al., 2010).

Thereby, atmospheric pollution due to ships raised in the last decades concerns in the scientific community and in policy-makers, and global efforts have been devoted to regulate and prevent risks from ship emissions, especially in harbor cities and coastal areas.

This work reviews the current knowledge of the impacts of shipping to atmospheric pollutants emissions, contributions to local air quality in coastal areas and harbor-cities, and the impacts to health indicators. The effects of legislation standards, relative to sulfur content in marine fuels and enforcement of Emission Control Areas (ECAs), on atmospheric pollution due to shipping is discussed. Furthermore, future perspectives and projections related to the increase of energy efficiency of ships and improvement on quality of fuels will be discussed.

Overview of Shipping Sector: Some Statistics

The massive increase in shipping has been driven by the growth in world trade depending on both institutional and technological factors. In 2018, Singapore, the Republic of Korea, Malaysia and the United States had the best worldwide connected hubs even if the top-20 bilateral connections were intra-regional, namely within Europe and within Eastern and South-Eastern Asia. Although financial crisis in 2009 and a relatively slow growth recorded since 2013, international seaborne trade volume reached 11 billion tons in 2018 (+2.7% compared to 2017), container traffic accounted for 793 million twenty-foot equivalent units (TEUs), that is larger than 4.7% with respect to the previous year (UNCTAD, 2019). As consequence of global trade, over recent years, tonnage has

increased considerably in all categories, especially for bulk carriers (about 71% of goods—coal, ores, grains, containers—were transported by dry cargoes in 2018), with an only decline for general cargo (i.e., oil tanker). Finally, in the same year the majority of harbor calls of ships, including ferries, roll-on roll-off, and passenger ships was from Norway.

Global GHG emissions, expressed on a CO₂-equivalent (CO₂e) basis, of total shipping registered by the International Maritime Organization (thereafter IMO) decreased in relative terms from 3.2% in 2007 to 2.5% in 2012. For 2012 this corresponds to 961 Mtons of CO₂e (816 Mtons are relative to international shipping), and about 97.6% is due to the sole CO₂ emissions (IMO, 2015). The multi-year (2007–12) average annual totals emissions are 20.9 Mtons and 11.3 Mtons for NO_x (as nitrogen dioxide - NO₂) and sulfur oxides, SO_x (as SO₂), from all shipping (IMO, 2015), representing about 15% and 13% of global NO_x and SO_x from anthropogenic sources reported in the IPCC Fifth Assessment Report (AR5). A successive study (Johansson et al., 2017) showed that global shipping emissions in 2015 were comparable to that of 2012 for NO_x but were lower (9.7 Mtons) for SO_x as a consequence of the use of low-sulfur content fuels in specific areas. Global emissions in 2015 (Johansson et al., 2017) were 1.5 Mtons (PM_{2.5}, i.e., particles with aerodynamic diameter less than 2.5 µm) and 1.35 Mtons (CO). The largest contributors at global level (more than 80% of the total) are container ships, cargo carriers, and tankers (i.e., emissions from commercial shipping). Broadly speaking, the largest emission of PM_{2.5} and SO_x, per unit area, occur in China Sea, in the sea areas of southern and south-eastern Asia, in the Red Sea, in the Mediterranean, in north Atlantic in proximity of EU coast, in the Gulf of Mexico and the Caribbean Sea, and along the west coast of United States. Shipping emissions over Europe represent 16%, 11%, and 5% of total NO_x, SO_x, and PM₁₀ (i.e., particles with aerodynamic diameter less than 10 µm) emissions even if there is a certain variability associated to the emission databases used (Russo et al., 2018). Given its importance in both health and radiative forcing, research efforts have also been devoted to investigate BC emissions from shipping that represent about 2% of global BC emissions (Lack and Corbett, 2012).

Global and Local Regulatory Framework

Environmental awareness on harbor system began to be of significant relevance as of the 1990s. The first adoption of institutional measures, by proposing a series of recommendations regarding environmental issues, was introduced in 1998 by the American Association of Ports Authorities (AAPA), which was based on an alliance between harbors of the United States, Canada, the Caribbean, and Latin America. Similarly, in Europe, the European Sea Ports Organization (ESPO) in 1994, published a first version of the Environmental Code of Practices.

As agency of United Nations, the International Maritime Organization, born in 1948 as Inter-Governmental Maritime Consultative Organization, or IMCO, and then changed to IMO in 1982, adopted the “International Convention for the Prevention of Pollution from Ships,” as modified by the Protocol of 1978 reaching to MARPOL 73/78. In 1997, a new Annex VI “Regulations for the Prevention of Air Pollution from Ships” was added entering into force on 19 May 2005. Successive amendments have been done for progressive improvement on the quality of fuels used for shipping to reduce NO_x and SO_x and PM emissions; furthermore, designated ECAs were foreseen. Regulation 14 sets the sulfur content of any fuel oil used on board ships, outside ECAs, not exceeding the following limits: 4.5% m/m prior to 1 January 2012; 3.5% m/m on and after 1 January 2012; and 0.5% m/m on and after 1 January 2020 (known as “IMO 2020”). A summary of regulations on the maximum sulfur content of marine fuels is shown in Fig. 1.

Figure 1 Sulfur content limits in marine fuels according to IMO and EU legislation.

Regarding NO_x, in October 2016, two new NO_x ECAs (the Baltic Sea and the North Sea) were introduced. As of 1 January 2021, within these areas all ships must respect defined mandatory engine standards or equivalent NO_x emission reduction technologies according to Tier III standards.

In addition to global IMO regulations, there are some local initiatives too. In Europe, after a long legislative effort, the latest limits for marine fuels are included in Directive 2016/802/EU, introduced by Directive 2012/33/EU amending Directive 1999/32/EC. As of 1 January 2015, EU zones designated as SO_x—ECAs (the Baltic Sea and the North Sea) have to ensure that ships use fuels with a sulfur content of no more than 0.1%. Furthermore, EU non-SECA passenger ships should use fuels with maximum sulfur content of 1.5% m/m and from 2010 onwards all ships at berth in EU harbors for more than 2 hours should use fuels with sulfur content of less than 0.1% by weight. China established (regardless of the MARPOL Convention) a sulfur limit of 0.5% m/m applied in some steps, designating three areas along the coastline—the Pearl River Delta, the Yangtze River Delta and the Bohai Rim waters coastline—defined “Domestic Emission Control Areas” (DECAs). First, as of 1 April 2016, the implementation of the regulation was effective only for berthing in specific harbors within DECAs, however, this limit was still higher compared to EU and US legislation (0.1% m/m). In 2018, extension to all harbors in the designated DECAs was applied until, starting January 1, 2019, all ships entering China’s coastal waters, during all operations, have been compliant with the limit of 0.5% m/m. Finally, several national initiatives have been proposed for future years (i.e., limits for inland waterways, extension of DECAs geographical boundaries, future IMO ECA implementation) in order to cope severe air pollution caused by shipping. In the United States, since 1 January 2014, the “Regulated California Waters” Phase II imposes to use 0.1% m/m sulfur content marine distillates within 24 nautical miles of the California coasts. In addition, CARB (California Air Resources Board) requires some ship categories (container, passenger, and refrigerated cargo) to connect shore power during berthing in California harbors.

To deal with the new IMO requirements ship owners have essentially three options: change to cleaner (with lower sulfur level) or alternative (i.e., liquefied natural gas, LNG) fuels, application of retrofitting technologies (i.e., scrubbers) and cold ironing. Each of these has strengths and weaknesses. Scrubbers require large initial investments due to installation on old engines of existing ships. According to a survey (EGCSA, 2018), exhaust gas cleaning systems are the best solution for the biggest ship companies (i.e., Maersk CEO), in fact 983 vessels (especially bulk carriers) were equipped with scrubbers as of 31 May 2018. Instead, although alternatives fuels could be a valid option, their availability and bunkering are still lacking, as well as potential incompatibility problems with current vessel’s engines. Finally, shore side electricity at berthing has been adopted in several harbors in Europe (i.e., Antwerp, Gothenburg), North America (Los Angeles, Vancouver, Seattle), in Alaska and California. This solution is recognized to reduce not only NO_x, SO_x, and PM emissions inside harbors near populated coastal cities, but also noise. However, barriers are represented mainly by energy and infrastructure costs, taxes, and technical issues due to different standards for the plug-in systems (voltage and frequency). In addition, the potential of shore side energy production through renewables should be further investigated.

Assessment of Shipping Impact to Atmospheric Pollutants and Human Health

The impact of shipping should be discussed considering, separately, emissions, contributions to concentrations (i.e., effects on air quality), and health effects. These are correlated but not linearly so that a reduction of emissions has different effects on air quality in specific sites depending on the distance from the emissions and the typical transport and dispersion conditions due to winds. Health effect are not related only to concentration of pollutants but to population-weighted concentrations (i.e., to population exposure) meaning that a degradation of air quality in a specific area has very different impact on public health depending on the density of population in that area.

Global pollutant emissions from ships are mainly due to commercial traffic (but this could not happen at local scale) and about 70% of these are released within 400 km from coastlines (Eyring et al., 2005). In harbor ship emissions represent only a small fraction of the global emissions associated with shipping (Dalsøren et al., 2009). However, they can have important environmental effect on coastal regions in Europe, Asia and USA, which often have harbors located near urban and industrial centers. They come from different sources: emissions during maneuvering, during hoteling because several ships at berth needs to power their services with auxiliary engines, harbor-related emissions during loading/unloading of ships including road traffic in the internal area of harbors. This last kind of emission is strictly related to harbor logistic and infrastructures. Hoteling phase is the largest contributor to local emissions in several harbors considering that this phase lasts generally much more than maneuvering. Recent studies in some Mediterranean harbors (Merico et al., 2017, 2019) showed that, at local scale, showed that in harbor emissions of PM and NO_x are typically comparable with those of road traffic (of a small/medium size town), emissions of SO₂ are generally significantly larger than those of road traffic because of the much more stringent standard of sulfur content in road vehicles fuels, emissions of CO are generally lower than those of road traffic. Globally, the implementation of the new 2020 standard will produce a 75% reduction in SO_x emission from ships and a reduction of about 49% of particulate matter including both primary and secondary sulfate (Sofiev et al., 2018). No significant reduction is foreseen for ship-related emissions of NO_x and CO₂. Recent studies in DECA area of Pearl River Delta (China) showed that the use of low sulfur fuels could actually increase VOCs emission factors of ships and this threaten to increase ozone (O₃) formation in harbor cities (Wu et al., 2020).

The influence of ship traffic is not easily identifiable in most areas where land-based sources (industrial settlements, railway, and urban agglomerates) co-exist and/or for complicated meteorological conditions. The quantification of the impact of harbors on local air quality has been performed with different approaches such as large (global, continental, and/or national) scale source-oriented modeling (Monteiro et al., 2018; Sofiev et al., 2018) or at local scale (Merico et al., 2019) using transport and dispersion codes based on estimates of shipping emissions. Other studies rely on receptor-oriented models based on specific measurement

campaigns in coastal or harbor areas and statistical methods or receptor models to estimate shipping contributions. Widely used receptor-oriented approaches are the use of high temporal resolution measurements correlated with wind conditions and ship traffic (Contini et al., 2011; Ledoux et al., 2018) or the use of chemical composition of PM and specifically the V concentration and the V/Ni ratio considered as tracer of ship emissions (Cesari et al., 2014; Viana et al., 2009). Each method has advantages and drawbacks and particular care should be placed in comparing results obtained with different approaches and having different uncertainty. Scientific studies based on receptor-oriented approaches for the evaluation of shipping contributions to PM_{2.5} or PM₁₀ in different coastal/harbor sites worldwide have been reviewed in this work and results are reported in Fig. 2 in terms of relative impacts compared to measured concentrations. In some areas more than one site have been analyzed or the same site was involved in more than one study. In these cases an interval of impacts is reported in Fig. 2.

Contributions to PM_{2.5} range between 3% and 9% in US sites, between 0.2% and 14% in Europe and are generally larger in East Asia especially near busy harbors in China (between 2.4% and 25%). In Europe there is a clear gradient with larger contributions in Mediterranean Sea compared to northern Europe. Another aspect is that the contributions to PM₁₀ are generally lower (in relative terms) compared to those to PM_{2.5}. This is because ship emissions are dominated by particles of small size. Limited studies compare the impact of shipping to particle mass concentrations (PM_{2.5} or PM₁₀) with impact to particle number concentration (PNC). These are not expected to be the same because mass concentrations are dominated by relatively large particles (diameters > 1 µm), instead, PNC is dominated by ultrafine particles (diameter < 0.3 µm) or nanoparticles (diameter < 0.1 µm) that have low contribution to aerosol mass. The results of some studies in the Mediterranean area in which impacts to PNC and PM_{2.5} are estimated using the same receptor-oriented approaches are reported in Fig. 4. These show that shipping emission contributions to PNC are expected to be 3–4 times larger than those to PM because combustion particles emitted by ships are dominated (in number) by ultrafine particles as observed also in other studies (Diesch et al., 2013; Gobbi et al., 2019).

The studies regarding impact of ships to gaseous pollutant concentrations done using receptor-oriented approaches are more limited. A review of current data for Europe is reported in Fig. 3. Results show that the relative contributions to SO₂ and NO_x are generally larger compared to the contributions to PM_{2.5} or PM₁₀. Contribution to CO is typically comparable with that to PM (Merico et al., 2019). At local scale, ship emissions bring to a depletion of O₃ because of titration due to NO releases (Merico et al., 2016; Ledoux et al., 2018). This is a local scale effect because at larger distances from the emissions, in diurnal hours, the excess of NO₂ due to ships could actually increase the production of O₃, especially during summer. Large-scale numerical modeling results indicated that shipping emissions enhance surface O₃ concentration by 5%–10% in the Mediterranean Sea (Aksoyoglu et al., 2016). Considering current thresholds of air quality standards in Europe and in several other areas worldwide, NO_x emissions from ships could lead to exceedances of legislation standard for NO₂ (or NO_x) concentrations representing a critical aspect that should be addressed in future mitigation policies.

There are evidences that the use of low sulfur fuels reduced the contribution to SO₂ concentrations and to secondary and primary PM in coastal areas (Tao et al., 2013; Contini et al., 2015; Liu et al., 2018). It has also been observed a reduction in V concentrations even if total contribution to metals in PM₁₀ was not significantly affected (Gregoris et al., 2016). Furthermore, shipping emissions could significantly contribute to PAHs in gaseous and particulate phases. In some Mediterranean harbors contributions from 50% to 70% (locally) was estimated and no significant reduction as a consequence of the use of low sulfur fuel was observed (Donato et al., 2014; Gregoris et al., 2016).

There are evidences, from epidemiological studies, of a negative impact of shipping to health. Estimates are done using population-weighted concentrations of ship-related pollutants and specific exposure-response (ER) functions. There are significant variability on the results obtained according to the spatial resolution of the analysis, to the population databases used and to the ER functions considered. However, all studies indicate relevant influence of shipping on mortality and morbidity. Globally, about 60,000 premature deaths in 2010 and about 90,000 premature deaths in 2012 due to cardiopulmonary diseases and lung cancer were attributed to exposure to particulate matter emitted from international shipping (Corbett et al., 2007; Winebrake et al., 2009), and 400,000 premature deaths per year due to shipping are predicted for 2020, under business-as-usual assumptions (Sofiev et al., 2018). In east Asia between 14,500 to 37,500 premature deaths were estimated as due to PM_{2.5} related to shipping (Liu et al., 2016). A study in the area of Sidney (Australia) showed for 2010/2011 that about 1.9% of the region-wide annual average population weighted-mean concentration of all natural and human-made PM_{2.5} was attributable to ship exhaust, and up to 9.4% at suburbs close to harbors. These figures lead to an estimate of 220 years of life were lost as a result of ship exhaust-related exposure (Broome et al., 2016). The use of low sulfur fuels decreases average ship-related concentrations (mainly for PM and SO₂), consequently, population exposure is lower and this reduces health effects of shipping emissions (Broome et al., 2016; Barregard et al., 2019). Globally, the projection of the new fuels standard enforced in 2020 will reduce premature mortality from 430,000 to about 250,000 and will also reduce morbidity by 54% (Sofiev et al., 2018). These figures represent about 2.6% global reduction in PM_{2.5} cardiovascular and cancer deaths and about 3.6% global reduction in childhood asthma.

Emissions from ships could alter radiative balance (influencing climate) through the simultaneous releases of pollutants having positive (CO₂, BC) and negative (SO₂) radiative forcing (RF). NO_x emission has both positive RF due to O₃ formation and negative RF due to enhancement in methane (CH₄) loss. The net balance on short term is a negative RF, around -0.4 W/m² in 2005 (Eyring et al., 2009), however, on long term, the accumulation of CO₂ due to its slow removal is expected to turn the cooling effect to a warming effect (Fuglestedt et al., 2009). The effect of using low-sulfur fuel is somewhat complicated because there is a decrease on secondary sulfate in ship-related aerosols that generally have a cooling effect. Projections indicate that this reduction of sulfur will change optical properties of released aerosol reducing cooling effect of ship aerosols by about 80% corresponding to a 3% increase in

Figure 2 Relative (%) shipping contribution (excluded mixed industrial and shipping sources) to $PM_{2.5}$ (black triangle) and PM_{10} (green circle) worldwide. Source: Data is taken from the following references: Donateo et al. (2014), Lang et al. (2017), Nakatsubo et al. (2016), Saraga et al. (2019), Sarigiannis et al. (2017), Sorte et al. (2020), Viana et al. (2014).

current estimates of total anthropogenic radiative forcing (Sofiev et al., 2018). This suggests that future mitigation strategies and policies should target both aspects; health and climate, as two faces of the same medal. This could be achieved, for example, with actions targeting a joint reduction of air pollutants and GHGs.

Figure 3 Relative (%) shipping contribution to gaseous pollutants across Europe. Source: Data is taken from the following references: Gariazzo et al. (2007), Ledoux et al. (2018), Merico et al. (2016; 2019), Murena et al. (2018), Viana et al. (2014).

Future Perspectives and Conclusions

A non-negligible share of global anthropogenic emissions of atmospheric pollutants (both in gas and particulate phases) and of GHGs is associated with shipping. At global level container ships, cargo carriers, and tankers are the largest contributors (more than 80% of total shipping emissions for most of the pollutants) but at local scale, in coastal areas and near harbor-cities, this generalization is not possible and cruise/passenger or ferries could have a prominent role.

Ship traffic contributions to atmospheric particulate matter (PM_{2.5}) worldwide ranges typically between 0.2% and 14% in Europe, with largest impacts in the Mediterranean area; between 3% and 9% in North America; and between 2.4% and 25% in Asia, especially in busy harbors in China. The general trend is that contribution of shipping to ultrafine (i.e., diameter < 0.3 μm) particle number concentration (PNC) is 3–4 times larger than the contribution to mass concentrations (either PM_{2.5} or PM₁₀). This would suggest that PNC could be a more suitable metric for investigating the role (and future trends) of shipping to atmospheric particulate matter. Contribution to gaseous pollutants like NO_x, SO₂, and CO are generally larger than those to particulate matter (PM_{2.5} or PM₁₀) and, considering current legislation thresholds in different continents, shipping could play a role in local exceedances of NO₂/NO_x thresholds.

The use of low-sulfur fuels as well as the establishment of ECAs (or DECAs) in specific areas brought to a reduction of SO_x, PM primary emissions, secondary sulfate in particles, and BC leading to a reduction of the impacts to measured concentrations especially near coastal and busy harbor areas. However, it had low or negligible effect on reduction of NO_x, total metals in PM (even if a certain reduction on specific metals like V was observed), and PAHs. Further, there are evidences that the use of low-sulfur fuels increases emission factors of VOCs with potential influence on secondary O₃ formation (that has negative effects on health). This suggests that future policies should take into account also non-criteria pollutants to maximize the positive effect on air quality. Epidemiological

Figure 4 Relative (%) impacts to PM_{2.5} and PNC in four Mediterranean harbor cities.

studies showed that reduction of sulfur content of fuels brought a decrease of premature mortality and morbidity due to ship emissions globally and that ECAs/DECAs had similar beneficial effects at local scales in the interested areas.

The application of the new legislation (started in 2020) will bring a further reduction of shipping emissions. Projections indicate that this will lead to a reduction of 34% of ship-related premature mortality and 54% for morbidity. Despite this reduction there will still be about 250,000 deaths annually so that there will still be margins for further improvement. Specifically, further improvements on fuels are possible as well as establishment of additional ECAs, however, it has to be done with attention to the economic aspects in order not to affect the competitiveness of specific harbors or routes and with attention to climate. Low sulfur fuel reduces radiative cooling of ship-related aerosols and projection indicates a 3% increase of the total anthropogenic radiative forcing. Therefore, future stronger policies for shipping emissions should be focused on achieving both climate and health targets as could be done by jointly reducing atmospheric pollutants and GHGs. This becomes particularly important in climate hot spots like, for example, in exploiting new Arctic ship routes.

Future joint benefits for GHGs and air pollutants could come from the improvement of energy efficiency operational indicator (EEOI) of ships that will reduce directly fuel consumption. Further benefits, at local scale, could be achieved by improving sustainable and energy efficiency strategies and policies in harbors moving toward a “green” development of seaports. For example, harbor logistics could reduce emissions of harbor-related activities at loading/unloading of ships. This is a minor component of global emissions but could be relevant on local scale. Furthermore, cold ironing to partially/totally provide electricity to ships from the docks could significantly reduce emissions especially if electrical power is at least partially obtained from renewable sources.

Noise Pollution Overview

Definition of Noise Pollution

The growth in travel demand over the last decades has led to a range of significant transport-related policy problems. Environmental externalities produced by transportation systems prevail. Noise pollution is one of the most pressing environmental problems associated with transportation and it has become an important element of the sustainable development. Noise is a growing concern among both the general public and policy-makers.

Noise pollution (sound pollution, environmental noise) is the propagation of anthropogenic noise with harmful impact on human health and well-being or animal life. It refers to the elevation of natural ambient noise levels due to sound-generating human activities, which may be wanted (music, sirens, sonars) or unwanted (i.e., transport-related noise).

Noise from transportation is the world's most prevalent form of environmental noise. The major source of noise pollution both inside and outside urban areas is road traffic. Noise from railways and aircrafts has a much lower impact in terms of overall population noise exposure, but both remain significant sources of localized noise pollution. European Environment Agency (EEA, 2019) has estimated that in Europe 78.2 million people are exposed to noise in excess of 55 dB L_{den} (55.1 million to noise in excess 50 dB L_{night}) due to road traffic, while the number exposed to the same level from railway is 10.3 million, from aircraft—3.0 million and that from industry—0.8 million.

Directive 2002/49/EC relating to the assessment and management of environmental noise (the Environmental Noise Directive—END) is the main EU instrument to identify noise pollution levels and to trigger the necessary action both at Member State and at EU level.

Noise Indicators and Measures

Environmental noise monitoring is the measurement of noise in an outdoor environment. The most common approach to sound intensity measurement is to use the decibel scale $I(\text{dB}) = 10\log_{10}(I/I_0)$. Decibels measure the ratio of a given intensity I to the threshold of hearing intensity I_0 , so that this threshold takes the value 0 decibels (0 dB).

Sound intensity is a sound power per unit area measured in Watts/m². Standard threshold of hearing intensity $I_0 = 10^{-12}$ Watts/m². The nominal dynamic range of human hearing is from the standard threshold of hearing I_0 to the threshold of pain $I_p = 10^{13} I_0 \approx 130$ dB.

Intensity of selected anthropogenic sounds: quiet library—30 dB, quiet room—40 dB, normal conversation—60 dB (intrusive), moderate traffic—75 dB, heavy traffic—85 dB (annoying), subway, motorcycle, truck traffic—90 to 100 dB (load), garbage truck, pneumatic drill—100 dB (very loud), emergency response siren, jet takeoff—120 dB, jackhammer—130 dB, jet engine—140 dB (painfully loud).

The audible spectrum of humans is from about 20 Hz to 20 kHz, but the upper limit in average adults is often closer to 15–17 kHz. All mechanical waves in this range can be associated with sound pollution.

Authoritative agencies set health protective noise thresholds, the excess of which may cause discomfort or lead to injuries and illnesses:

- US Environmental Protection Agency: day-night average sound level, indoors: $L_{dn} = 45$ dbA, dbA is an A-weighted decibels.
- World Health Organization:
 - equivalent continuous sound level, outdoors: $L_{eq} (16h) = 55$ dbA.
 - average nighttime noise level, outdoor: $L_{night} = 40$ dbA.

World Health Organization (WHO, 2018) strongly recommends reduction of average noise levels from road traffic below 53 dB L_{den} (45 dB L_{night}), from railway traffic below 54 dB L_{den} (44 dB L_{night}) and from aircraft below 45 dB L_{den} (40 dB L_{night}). It also recommends that policy-makers implement suitable measures to reduce noise exposure from transport in the population exposed to levels above the guideline values for average and night noise exposure.

Health Impacts From Noise Pollution

Exposure to noise can lead to auditory and non-auditory effects on health. Noise leads to hearing loss and tinnitus. Noise is a non-specific stressor having an adverse effect on human health, especially following long-term exposure. These effects are the result of psychological and physiological distress, as well as a disturbance of the organism's homeostasis and increasing allostatic load (WHO, 2018). Noise may negatively interfere with a child's learning and behavior, can damage physiological health, cause hypertension, high stress levels, sleep disturbances, and other harmful and disturbing effects (WHO, 2018). High noise levels can contribute to cardiovascular effects in humans and an increased incidence of coronary artery disease (Münzel et al., 2018). In animals, noise can increase the risk of death by altering predator or prey detection and avoidance and, interfere with reproduction and navigation (Kaselo and Tyson, 2004).

Road Traffic Noise

Sources of Traffic Noise

Noise from road transport vehicles has been of interest to researchers for many years. A great deal of work in this respect has been devoted to the noise to which a road user is exposed. Intensive work to reduce noise inside means of transport has continued to this day since the 1970s. Far less attention has been paid so far to reducing noise that affects the environment in which road transport vehicles operate (Guarinoni et al., 2012). Due to the number of road transport means, it is this mode of transport that generates the most noise. Both vehicle groups and individual vehicles are the sources of noise. Groups of road vehicles are most often found in urbanized areas and on very busy roads. The noise from such vehicles has the nature of continuous buzz or noise and its intensity may vary depending on the time of day and peak hours. Individual vehicles generate short-term noise that can occur anywhere.

Road noise is a combination of noise from the vehicle's drive system (engine noise) and noise caused by the interaction between the vehicle's tires and the road pavement (rolling noise). The noise level generated by a vehicle is mainly dependent on the speed at which the vehicle is running and the engine speed. As the speed increases, the engine noise gives way to rolling noise.

The vehicle drive system noise mainly consists of engine noise. Today it is usually an internal combustion engine. In addition to the combustion of the air-fuel mixture itself, noise is generated by the exhaust system, the air intake, fans, and auxiliary equipment.

Rolling noise is influenced by, among other things (Bernhard and Sandberg, 2005): noise from the impact of the vehicle's tyres on the road pavement, aerodynamic noise generated by the air pressed by the tyre in between the tread of the tyre and the road pavement, noise from vibrations of the tyre tread and unevenness of the road pavement, noise from slipping of the tyre when it comes into contact with the road pavement, and airborne noise generated by the air surrounding the vehicle.

This noise is further enhanced by a phenomenon known as the "horn effect." The geometry at the tyre/road point of contact forms the shape of a horn, which causes the high radiation of the noise emitted at this point. The tyre width, tread pattern and vehicle load also influence the rolling noise level. Of course, this type of noise will also be greatly influenced by the type of pavement on which the vehicle is running.

An additional source of noise from road transport is the horn. In many countries abuse of the horn can be punishable by police. Studies on noise from road vehicles do not take the horn sound into account.

Road Traffic Noise Standards

The main piece of EU legislation that defines the permissible levels of noise affecting humans and their environment is Directive 2002/49/EC (the Environmental Noise Directive—END). This Directive relates to the assessment and management of environmental noise, while indicating the measures necessary to reduce noise.

Another piece of legislation regulating noise from road transport vehicles is the European Directive (70/157/EEC) adopted in 1970. The Directive refers to the permissible noise level and exhaust system of motor vehicles. Since its adoption in 1970, it has been amended several times in order to adapt it to technical progress and changing vehicle structures. Currently, the content of this directive is included in directive No. 2007/34/EC of 2007. The directive introduces limits on the noise generated by motor vehicles depending on the vehicle category. The noise limit for passenger cars with a maximum of 9 seats is 74 dB. The noise limit for vehicles with a DMC of up to 3.5 and the engine power of not less than 150 kW intended for the carriage of cargo is 80 dB.

Another piece of legislation to limit noise emissions from road transport vehicles is directive (Directive 2001/43) of 2001. This directive applies to tyres of motor vehicles and their trailers and to their fitting. This directive divides motor vehicle tyres into classes. For each class of tyres and their tread widths, permissible noise limits are set, which vary from 70 to 79 dB.

Technical and Law Counteractions to Traffic Noise

Noise from means of transport can be reduced directly at its source or indirectly in the environment of its users (*At-source versus end-of-pipe measures*). The most commonly used methods of noise reduction in the user environment include the use of noise barriers, soundproof windows and proper urban planning (Bernhard and Sandberg, 2005).

Measures to control noise at its source include: legal regulations, regulations concerning the type of road pavement, regulations concerning the noise from the vehicle's drive system, regulations concerning the tyre noise level, the way the driver drives the vehicle, traffic management especially in urban areas (e.g., restrictions on traffic for heavy goods vehicles, reduction of traffic volume in selected areas, speed reduction, introduction of electric vehicles) combined with the transfer of passenger flows from private cars to public transport.

The research indicates that it is the most effective to eliminate noise already at its source (EC, 2004). So far, by far the most effective and cost-efficient method of noise reduction at source is the legislation that defines acceptable noise levels already at the stage of production of road transport vehicles, their equipment or tyres. Legislation towards setting noise limits for means of transport allows for noise reduction at a relatively low cost, as state-of-the-art engines and tyres already perform much better than current limits. Tightening the limits in this direction results in only minor additional costs for road vehicle manufacturers.

Railway Noise

Sources of Railway Noise

Railway is another mode of transport that causes environmental pollution through noise emissions. The basic sources of noise generated by rail transport include: noise from rolling stock, noise from the operation of equipment auxiliary to the operation of rail transport, aerodynamic noise, noise generated by signal equipment, and others (Murphy and King, 2014; Thompson, 2009).

Noise from rolling stock can be divided into four groups (EC, 2014):

- stationary noise,
- starting noise,
- the running noise, and
- noise inside the driver's cab.

Stationary noise is generated by railway vehicles when they are not in motion but are prepared for the run. Excessive noise from railway vehicles can be generated by a number of devices built on the vehicle—such as converters, motors, inverters, compressors, vehicle door closing and opening sounds, warning sounds before doors close or sounds generated by a system of toilets made in the so-called closed circuit. This noise is a nuisance both to those outside and inside the vehicle. Nevertheless, it is measured outside the vehicle.

Starting noise is associated with the railway vehicle or vehicles being put into motion. In order to do this, the traction vehicle must be powered at an appropriate level, which causes the noise emitted to be much higher than when running in uniform motion, for example. This noise is a nuisance both to those outside and inside the vehicle. Nevertheless, it is measured outside the vehicle.

Running (rolling) noise is the noise generated by the railway vehicle when running in uniform motion at 80 km/h and possibly 250 km/h. This noise is a nuisance both to those outside and inside the vehicle. Nevertheless, it is measured outside the vehicle.

The last type of noise from rolling stock relates to the interior of the driver's cab. A human being—an operator—a train driver drives a traction vehicle all the time. Therefore, the noise he is exposed to must meet strict standards due to the need for the highest level of safety and comfort. This noise is only onerous for people inside the vehicle and measurements are taken there.

The running of the train involves the need for authorized staff to operate a number of safety devices and to perform other accompanying rail transport operations. It is necessary, among others, to change the position of railway switches and derails, to

display a permitting signal at a semaphore, etc. Operation of these devices involves the emission of sound at appropriate levels. Therefore, there may be a risk of noise occurrence. Therefore, it is necessary to properly protect the devices against noise generation.

Aerodynamic noise is associated with a railway vehicle overcoming an obstacle resulting from an air barrier. When components of a railway vehicle try to “break through” the air medium, sound is generated. The higher the speed, the higher the intensity of the sound and the possibility of noise occurrence. When designing a vehicle, designers must act in such a way that the shape allows the least possible negative impact on noise generation.

The last group of devices that cause negative noise generation are signal devices mounted on the railway vehicle, which allow the driver to draw the attention of other traffic participants. Their use is associated with the need to maintain an adequate degree of safety. Currently three types of devices are used: whistle, high-pitched siren, and low-pitched siren. Each device should be audible from a suitable distance, but it must also comply with noise standards.

Railway Noise Standards

The limit values for stationary noise are expressed in terms of sound pressure. Under appropriate conditions, the equivalent continuous sound level for the vehicle concerned, the equivalent continuous sound level for the vehicle concerned taking into account the air compressor, and the corrected and time-constant sound level taking into account the impulse noise emitted by the exhaust shall be measured. The limit values depending on the type of railway vehicle are set in the range of 64–85 dB (EC, 2014).

Starting noise is also measured as a maximum corrected and time-constant sound level under appropriate conditions. Limit values are dependent on the type of vehicle and its power or maximum speed and take values between 80 and 87 dB (EC, 2014).

As already mentioned earlier, the running noise is measured at 80 km/h and/or 250 km/h under appropriate measurement conditions. Limit values express an equivalent continuous sound level and depend on the type of railway vehicle. For 80 km/h, the values are taken from 79 to 85 dB and for 250 km/h from 95 to 99 dB (EC, 2014).

The noise inside the driver’s cab shall be measured as an equivalent sound level close to the driver’s ear. Its limit values are dependent on the sound speed and emission values and they take values between 78 and 95 dB (EC, 2014).

Technical and Law Counteractions to Railway Noise

For the Member States of the European Union, the relevant document is Commission Regulation (EU) No 1304/2014 of 26 November 2014 on technical specifications for interoperability relating to the subsystem “Rolling stock — noise”, amending Decision 2008/232/EC and repealing Decision 2011/229/EU Text with EEA relevance (EC, 2014). This document describes the conditions for implementing interoperability (uninterrupted train running), including from the noise point of view. It is essential for the introduction of a single railway system throughout the European Union.

Aircraft Noise

Sources of Aircraft Noise

Air transport is one of the most developing branches of transport. Air transport allows to reach one’s destination very quickly and is one of the safest means of transport. Negative factors characterizing this branch of transport include its high emissivity of harmful compounds to the atmosphere and its noisiness. Sources of noise in air transport can be analyzed in several dimensions (Murphy and King, 2014), that is:

- noise generated by engines (propeller or jet engines), while the noise generated by jet engines results from the high speed of throwing gases into the atmosphere;
- aerodynamic noise, associated with airflow disturbances through elements such as wings, flaps or landing gear, can vary in different phases of flight.
- noise generated by equipment such as on-board generators for starting engines or pressure generation systems, and
- noise generated by ground operations such as aircraft taxiing, aircraft preparation, and maintenance passenger handling.

There are many factors that influence the noise level for particular sources (e.g., runway surroundings, weather conditions). Different aircrafts can generate different noise levels at different flight phases and at different airports.

Another source of noise is helicopter traffic. In this case, the engine generates noise through a “blade-slap.” This is the impact of the blade on the air turbulence generated by the preceding blade. In this case too, there is aerodynamic noise and generated by the helicopter’s additional equipment (Wilson, 2006).

Aircraft Noise Standards

International legal regulations on aircraft noise are implemented by specialized organizations that develop and implement international regulations governing the safety of international air navigation and support the development of air transport to ensure safe

and orderly development, such as the International Civil Aviation Organization (ICAO), Airport Council International (ACI), Directives of the European Union and European Parliament, US Federal Aviation Authority, Joint Aviation Authorities.

Air transport noise legislation addresses, inter alia, issues related to the implementation of noise-reducing procedures or appropriate air traffic management and planning both in the airspace and on the tarmac. In order to manage noise, ICAO has clarified a number of operational measures implemented at the time of take-off or landing, which are divided into the following areas:

- Operational measures reducing the level of emitted noise, for example, modern aircraft designs that minimize aerodynamic noise as well as the noise generated by aircraft propulsion system.
- Operational measures maximizing the distance between the aircraft and the ground.
- Operational measures targeting noise to less populated areas.

There are no specific provisions on the level of noise emitted by means of air transport, as well as actions and measures to protect against this type of noise. Individual solutions should be developed by individual authorities. However, as indicated in the WHO (2018) report, it is strongly recommended to reduce aircraft noise levels below 45 dB L_{den} for average noise exposure and below 40 dB L_{night} for night exposure.

Technical and Law Counteractions to Aircraft Noise

Measures to reduce aircraft noise can be considered under the following aspects: the development of modern engine propulsion systems, aircraft design and components, air traffic management methods, and methods to mitigate airport environmental noise.

Significant progress in aircraft design has been made since the 1950s of the 20th century, which lead to a reduction in noise level. It is known that today's aircrafts are 20 dB quieter than those designed in the beginning, which means that individual aircrafts are around 75% quieter (Guarinoni et al., 2012). Engine noise is one of the main factors influencing overall air traffic noise level. The reduction in noise results from a combination of changes in engine cycle parameters and design features. A key noise reduction measure is the renewal of an individual airline's fleet and the introduction of advanced aircraft technologies and solutions (Alonso et al., 2017) or the minimization of noise through appropriate aircraft design (Smith, 2004). An example is the creation of a silent SAX-40 aircraft with a Blended Wing Body (BWB) design (Graham et al., 2014).

Air traffic management plays an important role in the noise reduction process (Clarke, 2003). By using state-of-the-art navigation systems such as Area Navigation (RNAV) with the Global Positioning System (GPS) or Instrument Landing System (ILS) it is possible to control aircraft more precisely on approach to landing and take-off and thus to avoid inhabited or noise-sensitive areas.

The main measure to minimize aircraft noise around airports is the implementation of certain noise management measures. These measures include the development of models for the assignment of aircrafts with different engine types to specific runways at landing or take-off, the development of new arrival and departure procedures, the imposition of penalties on airlines for exceeding the noise limits. Minimizing the departure and arrival routes in the airspace of a terminal is another action carried out to reduce air noise.

The classification of noise abatement measures is shown in Table 1. In general, measures can be classified as legal actions as defined in directives, regulations, organizational actions to minimize noise through appropriate air transport traffic management, for example, route planning, and technical actions taking into account the application of the latest engineering and equipment solutions.

Urban Noise Pollution

Sources of Urban Noise Pollution: Car Traffic, Railway Transport, Heavy Goods Vehicles

Noise in urban areas is emitted by cars, trucks, motorcycles, buses, trams, and rail vehicles. It usually comes from traction systems (engine, braking system, exhaust system), wheel contact with road or rail and aerodynamic noise and vibration. The signals of rescue vehicles (fire brigade, ambulance, police), the operation of sanitary vehicles (e.g., garbage trucks), car alarms and horns are an

Table 1 Ways to reduce noise level in air transport

Legal actions	Organizational actions	Technical actions
• Flight reduction at night time • Financial penalties • Tax relief • Publication of best practice	• Assignment of appropriate aircraft types to runways • Organization of new arrival and departure procedures • The optimized route network in the terminal area • Noise maps	• Introduction of advanced air traffic management technologies such as RNAV • Fleet modernization • Noise barriers (barrier walls, embankments) • Quieter aircraft structures • New engine structures

important element of the city's noise environment. The noise is amplified and directed by tall buildings and compact developments along the streets.

The following traffic parameters are decisive factors for the noise level in the city: the traffic volume, the share of heavy vehicles and motorcycles, the speed of the vehicle flow, the traffic flow (stops and starts), the driving style and the use of horns (popular in Asian countries). The technical condition of vehicles (mainly related to age) has a major impact (Jacyna et al., 2017).

The noise level is also determined by the inclination of the carriageway section, the height of the location above the carriageway and the distance of the receiver from the carriageway, the texture and material of the pavement (concrete, asphalt, cobblestone, sound-absorbing surfaces), the terrain, the development of the surroundings (grass, shrubs, trees).

Noise Standards in Cities

The permissible noise level in a city may be limited by the authorities. Restrictions affect traffic organization and infrastructure design. During the daytime, restrictions to about 50–65 dB, WHO (2018) strong recommendation is 53 dB and at night to about 40–55 dB (WHO strong recommendation is 45 dB) and depending on the type of developments and function of the area. The limit values are often exceeded in the vicinity of most streets in the absence of protective devices, especially at night.

Technical and Law Counteractions to Noise Pollution in Cities

Reducing the noise level to the limit values is difficult, and therefore efforts are made to reduce the noise nuisance. A 3–5 dB reduction in the noise level has a noticeable effect.

Methods to reduce noise at source (emission zone):

1. Related to the vehicle and the driver:
 - a. Vehicle design (suspension, flow coefficient), engine design, type of tyres.
 - b. Technical condition and control of illegal modifications to exhaust systems.
 - c. Driving style and culture.
2. Design of infrastructure:
 - a. Location of the road and its surroundings—moving the road away from protected areas, elevation of the road (excavation, tunnel, partial covering, etc.),
 - b. Use of partially noise-absorbing construction materials.
 - c. Use of so-called “silent pavements” (3–5 dB noise reduction).
 - d. Reducing road inclination.
 - e. Maintaining road pavements in good condition.
 - f. Appropriate shaping of the excavation slope using greenery.
 - g. Use of non-contact tracks and prefabricated elements containing damping elements (track linings, mats under tracks—noise reduction 6–14 dB).
 - h. Use of grass.
3. Traffic organization:
 - a. Road hierarchy: layout of primary (traffic) and secondary (access and local) streets.
 - b. Active traffic control (increasing traffic flow), minimizing the number of stops.
 - c. Exclusion of traffic of selected groups of vehicles (temporary, area, competence).
 - d. Speed limiting (marking, speed cameras—reduction by 2 dB/10 km/h). Maintaining the speed of 30–50 km/h (with the predominant share of vehicles up to 3.5 t) results in a minimum noise level emission.
 - e. Using roundabouts (from 2 to 5 dB compared to a junction).
 - f. Promoting public transport, bicycles, and pedestrian traffic.

Reduction of noise at the receiver (nuisance zone):

- Objects located on the way of the sound wave—noise barriers (up to several dB), earth embankments (up to 25 dB), green belts (approx. 0.5–5 dB/1 m width of a dense hedge), non-residential buildings (e.g., garages, commercial buildings).
- Location, shape and acoustic insulation of buildings, noise barriers on (and in) the façade.
- Change of function of a building exposed to noise.

In EU cities with more than 100,000 inhabitants, at noise-prone areas, the necessity of making acoustic maps was introduced (Directive 2003/49/EC of the European Parliament and of the Council of 25 June 2002) relating to the assessment and management of environmental noise.

Methods and Tools for Measurement and Modeling Noise Pollution

Noise Pollution Modeling

An important aspect of assessing the impact of transport on the environment is noise measurement and prediction. Planning of infrastructure, transport systems, and their assessment requires the use of prediction models that take into account many factors related to the traffic, the characteristics of infrastructure and the environment. These models, extended by estimating the noise propagation, allow the preparation of noise maps for a selected area (Jacyna and Merkisz, 2014; Jacyna-Golda et al., 2017).

Noise prediction and propagation models are developed on the basis of actual traffic measurements. They aim at forecasting the noise intensity from the point of view of the receiver. Measurements are made under laboratory conditions (from a single noise source) as well as under real conditions for specific environmental conditions and vehicle structure. Such tests allow to develop a function taking into account various factors and indicating the noise level in a given place. The documentation of individual models contains information about the method of real measurements, that is, the measuring device used—a microphone, its location in space, the measurement procedure—continuous measurements, at time intervals, sampling, measurement conditions—traffic intensity, speed, pavement, weather conditions, ambient noise. On this basis, it is possible to repeat measurements, verify the model, and/or develop modifications to the model for specific traffic conditions.

The main group of models is statistical models based on the measurement sample and determining the noise level function for a given indicator. This group is most often used in the planning of transport systems by governmental entities. The second group of models is heuristic models, most often based on the use of artificial neural networks to forecast noise levels. The research indicates that models taking into account ANN are more accurate than statistical ones (Nedic et al., 2014), but they are most often used in academic applications.

As indicated by the Garg and Maji (2014), noise models may take into account various aspects and factors influencing noise levels, the most popular ones include:

- Source characteristics influencing emissions at the point of origin, including speed, traffic intensity, rolling noise, engine noise, aerodynamic noise, continuous or impulse emission, traffic dynamics characteristics (acceleration, deceleration), direction of traffic, characteristics of the means of transport—structure, type of tyres, load capacity.
- Characteristics of the infrastructure and the environment, including terrain, buildings and development density, noise barriers, vegetation, type of pavement, weather conditions, number of road lanes, occurrence of junctions, tunnels, and bridges.

Depending on the nature of the considerations and the type of transport (road, rail, air, industrial), micro, mezo, and macro scale models can be distinguished.

Road, Railway, and Aircraft Noise Calculation Methods

Road traffic is the most common element of research on noise in transport, to some extent due to the popularity and prevalence of this mode of transport. Many prediction models have been developed over the years. The following models are often used in road traffic, for example:

- FHWA TNM—a model developed in the United States by the Federal Highway Administration (FHWA), which is essentially a software tool for assessing road noise emissions. It includes five categories of vehicles (light vehicles up to 4500 kg, medium vehicles between 4500 kg and 12,000 kg, heavy vehicles more than 12,000 kg, buses more than nine passengers, and motorcycles). It is used to assess the noise emission from highways or road network based on adjustment to a sound reference level. The model contains an extensive database of reference emission values from different vehicle types and for different traffic conditions or pavements.
- CNOSSOS-EU—a model developed for the needs of the European Commission. This model includes five categories of vehicles (light—up to 3500 kg; medium—more than 3500 kg with two-axes, heavy vehicles—with three and more axes, moped and motorcycles; and open category). The calculation includes the estimation of rolling noise and engine noise, taking into account a wide range of parameters including but not limited to: traffic flow volume, speed, type of pavement, weather conditions or driver behavior. The model is also used to predict rail, aircraft, and industrial noise.

The above models are only selected examples used in practice and for research. Often these models are developed and used for specific countries (e.g., USA, UK, Germany, Switzerland, France, Japan, Scandinavian countries), the additional models/tools frequently used include the following: CoRTN model, NMPB-Routes, ASJ RTN-Model, RLS90, Harmonoise, Son road, Nord, CadnaA, TRANEX, SoundPlan. Information on the characteristics, comparisons, and application of the above models can be found in the papers (Garg and Maji, 2014; Khan et al., 2018; Murphy and King, 2014).

In rail transport, similar to road transport, models are being developed to assess noise emissions and spread. Here too, the already mentioned CNOSSOS-EU model applies. It takes into account; inter alia, the characteristics of the railway vehicle, the presence of barriers and devices to limit the spread of noise as well as the characteristics of the track. The model takes into account up to six types of noise sources in the assessment of noise emissions: traction, aerodynamic, rolling, squeal, impact, and bridge (Murphy and King, 2014). Other examples of models include: Reken-en Meetvoorschrift Railverkeerslawaii (RMR), Calculation of Railway Noise

(CRN), Mithra-Fer, Sound from Trains Environmental Analysis Method (STEAM), U.S. Department of Transport—Federal Transit Authority Noise Model.

In air transport, sophisticated prediction models are also used, which are an important element and indicator of noise reduction in a given area. Aircraft noise level can be measured using various measuring methods and models, for example, Integrated noise model (INM), SoundPLAN, Environmental Noise Model (ENM), FAA—integrated noise model, ECAC-CEAC Doc 29, Information on noise models can be found in the paper, for example, (Filippone, 2014; Murphy and King, 2014). In the era of Artificial Intelligence development technology, fuzzy models are the advanced models for assessing noise in the airport environment (Diop et al., 2013).

What are Visual Impacts of Transport and Who is Affected?

The visual impacts of transport are the negative or positive effects of the physical appearance of transport infrastructure and motorized vehicles. These effects decrease the quality of trips and places and possibly affect travel behavior and use of public places; the well-being and residential satisfaction of the affected individuals; and the economic vitality and social cohesion of the affected neighborhoods.

Transport has two different types of visual impacts, depending on who is affected. The first type is felt by users of non-motorized modes (e.g., pedestrians, cyclists) and individuals who are not using the transport infrastructure causing the effect, but who live, work, shop, or visit the area where the infrastructure is visible. This impact is usually negative and has been described in the literature as “visual blight,” “visual intrusion,” or “visual pollution.” The second type of impact is felt by users of motorized vehicles (e.g., car and bus drivers and passengers). This impact is a mix of negative and positive aspects. The two types of impacts differ in terms of causes, consequences, solutions, and assessment methods. This article is therefore split into two parts, one for each type of impact, with the part on the impacts on users of non-motorized modes and non-users being lengthier because of the potentially extensive negative consequences of these impacts.

Visual Intrusion—Impact on Users of Non-Motorized Modes and Non-Users

Transport Infrastructure

Elevated roads and railways are the transport infrastructures most commonly recognized as causing negative visual impacts (**Fig. 1**). These infrastructures have a large imprint on the landscape and intrude on the visual field of pedestrians and people using public places next or underneath them, or looking at them from buildings. Elevated infrastructures can be disliked purely on aesthetical grounds, due to their size or appearance, or regarded as intimidating due to their size and position at higher level. The effect is aggravated in areas with multiple infrastructures at various heights and in areas with high-rise buildings, where some residents have elevated infrastructure near their windows.

Large transport infrastructures cause negative visual impacts even when not elevated. Motorways, multi-lane roads, and railways can be perceived negatively because of their size, which is incompatible with the scale of pedestrians, or because they are perceived as alien to the surrounding environment. Ports and airports may also be disliked because they are large single-use areas that include many buildings and other structures.

The negative visual impact often stems from specific elements of the infrastructure, rather than the whole infrastructure. Roundabouts, large road junctions, rail depots, areas with multiple rail service tracks, and large car parks, are particularly intrusive, as they occupy a large area that is off-limits to pedestrians (**Fig. 2**).

Often, the most visually disturbing elements are auxiliary structures. For example, overhead signs and billboards on motorways and roads intrude on pedestrians in streets nearby or below and on people at home. Again, size is the determining factor, as these signs are meant to be seen by people in vehicles moving fast. There is also extensive evidence that pedestrians dislike clutter caused by traffic signs and street furniture on urban streets, because of a visual disturbance effect above that caused by the obstructions that such elements cause on movement (**Fig. 3**).

Figure 1 Example of visual impact caused by elevated road infrastructure (Shanghai, China).

Figure 2 Example of visual impact caused by non-elevated road infrastructure (Brussels, Belgium).

Figure 3 Example of visual impact caused by clutter (Skopje, North Macedonia).

Lights from roads, ports, and airports also contribute to light pollution. Lights on tall poles along roads intrude on people's homes, affecting sleep patterns. Lights from transport infrastructure and vehicles, and their reflection, also contribute to urban sly glow, and lights on roads crossing natural areas disrupt wildlife. However, lighting also has positive aspects: it facilitates movement at night and increases the visibility of pedestrians, reducing fear of crime.

Visual intrusion may also arise because of elements that solve other problems. For example, noise barriers are often placed in areas where transport infrastructure cross residential areas, so they affect the view from peoples' homes. However, they may also reduce negative visual impacts if they are perceived as less obtrusive than the motorways or railways they cover—this depends on individual tastes and on the characteristics of the barrier, including the size, shape, materials, textures, and colors.

Another example is elements of the infrastructure that reduce the barrier effect for pedestrians. Pedestrians using footbridges are above large and busy transport infrastructures (roads or railways) and thus have a wider, unobstructed, sight of them. As an elevated element, footbridges also intrude on the visual field of pedestrians walking below and of people at home. Footbridges may also be perceived as unattractive because of their design, or lack of repair or maintenance. This is also the case of underpasses, which tend to be perceived as unattractive, unpleasant, and unsafe, because of insufficient lighting, poor design (lacking visually attractive features), and poor maintenance (leading to the appearance of visually unattractive features such as litter and graffiti).

While transport infrastructure has a mostly negative visual impact on pedestrians, some transport infrastructures can have positive impacts. This is for example the case of some iconic bridges (e.g., Sydney Harbour Bridge, Golden Gate Bridge in San Francisco) or even some visually attractive footbridges.

Motorized Vehicles

Pedestrians and people at home may also dislike the sight of motorized vehicles using the infrastructure, especially when the traffic has a large proportion of Heavy Goods Vehicles. People may dislike the design of vehicles or feel intimidated by their size, quantity, speed, or by particular situations (e.g., vehicles moving at fast speed in elevated roads). Sociologists have also noted that some pedestrians dislike the sight of private cars because of the perceived negative power relationship linked to the unequal distribution of roadscape.

These problems are exacerbated by glare from vehicle headlights on pedestrians at nighttime and reflections from the vehicles' metallic surfaces during daytime. This causes discomfort and reduces the amenity value of walking. It also causes distractions and reduces visibility, limiting pedestrians' ability to move safely along or across busy roads.

Motorized vehicles have negative visual impacts even when they are not moving. People often dislike the sight of parked cars as they are perceived to encroach on pedestrian space and more generally, on residential neighborhoods (Fig. 4). This effect is aggravated when cars are parked on pedestrian pavements.

Again, in a few cases, looking at motorized vehicles can be a positive experience. Trainspotting is a popular hobby in many countries. Some airports also have observations decks used by many passengers and non-passengers. Seeing ferryboats or canal boats can also be relaxing. Trams and funiculars are also a tourist attraction in many cities, such as Lisbon (Portugal) and Valparaíso (Chile).

Consequences of Visual Impacts

The negative impacts of transport on pedestrians and users of the affected area can lead to wider negative consequences, described below. While most of these have been mentioned in the literature, it is often only as a part of a list of hypothesized effects. There is still little empirical evidence on the magnitude of many of these effects, and on who is affected and under which circumstances—in contrast with the rich body of evidence produced about other negative local effects of transport, such as noise and air pollution.

Visual impacts reduce the perceived quality and people's enjoyment of the places (e.g., streets, squares, parks) that are next, under, or within sight of unattractive transport infrastructure. Often, the reaction is to avoid those places or, if that is not possible, to spend less time in them. The low visual quality of public places affects what Jan Gehl calls "optional" and "social" activities, that is, activities that are not "necessary" (e.g., waiting for bus) and only occur in places where people feel relaxed and comfortable (Gehl, 2010).

Figure 4 Example of visual impact caused by parked cars (Lisbon, Portugal).

The sight of visually intrusive transport infrastructure and traffic also reduces the perceived quality of walking and cycling trips as it limits the ability to perceive the surrounding environment and the enjoyment derived from walking and cycling. This restricts travel behavior, as people seek to avoid routes that are visually unappealing and choose other routes, which may be longer, have other problems (e.g., slopes), or have fewer trip attractors (e.g., shops). Visual impacts also create a psychological barrier effect that dissuades people from walking to the other side, separating neighborhoods and impeding people's ability to reach people and places on the other side.

Exposure to the visual impacts of transport can even affect people's image of cities and towns. The importance of visual perceptions has been recognized in the work of Kevin Lynch and Gordon Cullen in the 1960s (Lynch, 1960; Cullen, 1961), who called for planners to improve the visual quality of cities and towns. This has become imperative in the 21st Century, at a time when there is increased competition between cities to capture residents, business, and visitors based on high-quality public places.

For the individuals affected, the continued exposure to intrusive, unpleasant, or intimidating transport infrastructure and traffic, and the associated constraints on travel behavior and the use of public places, may have a negative impact on health and well-being. There is evidence, for example, that the view of one's home can aggravate or prevent the recovery from stress, depression, and even physical health problems.

The impacts on the quality of local places and the view from home also reduce residential and neighborhood satisfaction and can be a determinant of the choice of residential location. People may choose to live in different parts of the same neighborhood, or in a different neighborhood altogether, to avoid those impacts. However, empirical evidence has been non-conclusive, as the residential location choice is not explained by visual impacts alone, but by the cumulative effect of all negative aspects of living close to transport infrastructure, as well as the positive aspects (i.e., increased accessibility).

As people avoid the areas near or under transport infrastructure, these areas also become less attractive for commercial and leisure land uses and often become vacant—what Jane Jacobs called “border vacuums” (Jacobs, 1961). These can amount to a considerable proportion of a city's area—for example, New York City has an estimated 700 miles of elevated infrastructure. Some spaces may even become surrounded by large transport infrastructure on all sides, including above, and even when accessible to pedestrians, they become “no go” areas due to their unattractiveness—a situation described in fiction in J.G. Ballard's book “Concrete Island” (Ballard, 1974).

Unattractive places and neighborhoods also fare bad economically. There is extensive evidence that the quality of views influences the value of homes, and probably also of rents of shops and offices. It may also reflect on expenditure on businesses, via the effect on the number of trips, the time spent in places, and the propensity to spend money in those places. The price of hotel rooms and tourist attractions is also highly sensitive to the quality of views.

There is also a social cost. Areas next to walls or noise barriers or under large infrastructure tend to be neglected and attract vandalism and non-social behavior. The outcomes of some of this behavior (e.g., litter, unattractive graffiti) exacerbate the visual impact. All this affects people's perceptions of personal security, crime, attitudes towards the neighborhood, and ultimately community cohesion. At the same time, reduced walking and use of public places reduces social interaction, which shrinks local social networks and neighborhood social capital, and contributes to social exclusion of some people—again leading to reduced community cohesion.

The Subjectivity of Visual Impacts

Visual impacts are specific to a particular site at a particular time, affecting a particular group of people. As such, it is difficult to generalize research on these impacts, in contrast with other local impacts of transport, such as noise, air pollution, and even the barrier effect on pedestrians, which can be measured more or less objectively.

The problem depends on the spatial context—but there is not enough empirical evidence to know exactly how. For example, it is likely that the visual impacts of transport infrastructure are especially harmful when they are felt in natural areas, as the infrastructure will be perceived as an alien, unexpected, element. However, it could also be argued that visual impacts are more harmful in urban areas, in places that are used daily by people, on their way to work or walking around their neighborhood. Visual impacts may be attenuated in areas with attractive visual elements. But they can also be regarded as more impactful in their areas, as they detract from people's enjoyment of the attractive elements.

It also depends on the time context. Over time, individuals may adjust to the presence of visually disruptive transport infrastructure or motorized traffic. Local residents who experienced the change in the visual environment caused by a newly built infrastructure may also have different perceptions of the problem than those who have recently moved to the affected area.

The extent to which visual impacts are considered a problem also depends on personal perceptions. Visual preferences vary with culture. For example, in some cultures, minimalism is perceived positively, in others is perceived as boring. Studies on general visual preferences usually find differences according to age and gender, but there is not enough evidence to support his hypothesis in the case of transport infrastructure and motorized vehicles. It is likely, however, that the effect is stronger for people with mobility impairments, as it limits their ability to leave home or their neighborhoods.

How to Assess Visual Impacts

The most common approach to measure the visual impacts of transport infrastructure is to map viewsheds, that is, the area that is visible from a given point. The identification of intrusive infrastructure in viewsheds from a given point signals to a possible problem of negative visual impacts. Advances in GIS (Geographic Information System) data and methods, especially 3D models, have allowed for a more precise estimation of viewsheds. However, even with these methods, the approach is not usually taken over to the

next step, i.e. to measure the degree to which the infrastructure impacts on the people walking or spending time in the point where the viewshed is calculated.

Street audit tools (i.e., systematic assessments of the pedestrian environment) are sometimes used to capture visual aspects. However, these aspects are only a component in a larger assessment framework. Disaggregated results are not always presented. In addition, the aspects assessed usually refer to the whole visual character of the surrounding built environment, not the visual intrusion of transport infrastructure. The assessment also relies on the judgments of experts (usually only one), who may not be aware of how visual aspects affect the people who are exposed to them on a daily basis.

To address these limitations, surveys can be used to capture the perceptions and priorities of pedestrians or local residents with regards to the presence/absence of the transport infrastructure or particular characteristics of the infrastructure or motorized traffic. These surveys typically ask participants to rate or choose among different options, visualized in images, videos, and, increasingly, in immersive virtual reality environments.

In practice, visual impact assessments usually involve the production of various maps and a descriptive assessment synthesizing those maps. Assessments are often done in the case of new infrastructure but seldom in the case of changes that increase the visual impacts of existing infrastructure or interventions that reduce those impacts. There is also more guidance on how to assess the impacts on areas with natural or cultural interest, compared with impacts on residential areas.

The output of the assessment may also not be fully integrated into project appraisal. In fact, most official documents on transport appraisal mention visual impacts merely as an item on a list of social or environmental effects, not providing recommendations on measurement methods. As a result, visual impacts are either absent or included in a descriptive manner in cost-benefit analyses. As noted before, visual impacts have an economic value. However, it is not easy to pinpoint this value as a component of the value of the whole sensory experience of transport infrastructure and vehicles, which also includes exposure to dust, noise, vibration, and air pollution. Only a few academic studies have used stated preference surveys or hedonic analyses to capture trade-offs between property costs and visual aspects.

How to Reduce or Prevent Visual Impacts

There is increased political acceptance of interventions to remove obtrusive infrastructure, reflecting the shift of urban transport policy away from a car-centric paradigm and toward a livability paradigm (Anciaes and Jones, 2020). Elevated roads have been demolished in several cities. An emblematic project was the demolition of the Cheonggye Expressway in Seoul (South Korea) in 2005 to restore a stream and create a new park. The reduction of visual aspects is usually only one of the intended aims of these projects, the others being restoring pedestrian links and reducing noise and air pollution. Another solution is to screen the infrastructure with trees, rather than walls, which, as mentioned before, may aggravate the problem).

There is also growing interest in reconverting spaces under elevated roads and railways as shopping or leisure areas. Large-scale studies by the Design Trust for Public Spaces in New York (DTPS, 2015) and ARUP in several cities around the world (ARUP, 2018) have documented successful examples and provided guidelines for further interventions. A crucial component of these interventions is to make the spaces more visually attractive, with better lighting, greening, and public art. Unused elevated infrastructure can also be transformed into linear parks, for example the Promenade Plantée in Paris and the High Line in New York (Fig. 5).

Visual impacts can also be reduced by reducing traffic levels, especially of large vehicles. This can be achieved by restricting access of motorized vehicles to areas with high pedestrian traffic, at certain times.

There is also an increasing interest in the improvement of the public realm in roads, streets, and public places. Examples include reallocating road space to pedestrians and place activities (by restricting car movement or parking), the use of more visually appealing materials for street furniture and pedestrian pavements, and the removal of large and/or unnecessary street furniture.

Figure 5 Example of reconversion of elevated transport infrastructure (New York, United States).

Improving landscaping or adding trees also reduces the visual impact of roads. Issues such as light pollution tend to attract less attention, although there are regulations on the position and intensity of lights.

The View From the Road—Impact on Users of Motorized Modes of Transport

Visual aspects are also relevant for users of motorized modes (e.g., car, bus, and train drivers and passengers). Many of the aspects mentioned in the first part of this article also apply in this case, but there are important differences.

The view of the surrounding area contributes to trip quality and to the amenity value that drivers and passengers derive from the trip. Views of green or blue areas tend to be perceived positively, and views of industrial or derelict residential areas as negative. The research of Donald Appleyard and colleagues in motorways approaching large cities in the United States was one of the first to highlight the importance of the view from the road (Appleyard et al., 1964) and its implications for road design. A common result of this and other research is that, since cars move at a relatively fast speed, the visual experience of car users depends on the size of the visual field.

Car users are also affected by the view of the infrastructure they are using. In fact, people who use the same road frequently (for example, commuters) may not pay as much attention to the surrounding landscape (the way a visitor would do) as to details of the road and traffic, including walls and other elements at the road shoulder; the appearance of the road surface; signs; and the characteristics and motion of other vehicles.

Again, elevated roads and railways tend to have a negative visual impact, as they shrink the visual field of car users moving below. Complex junctions are also perceived as stressful to car drivers. The experience of driving in some junctions can even leave an imprint on the collective perception of wide regions around them. An example is the Gravelly Hill Interchange near Birmingham (England), popularly known since the 1960s as “Spaghetti Junction”—a nickname subsequently given to other similarly complex junctions around the world.

Despite being an auxiliary element, road landscaping is a crucial aspect of the visual experience of car users. Trees or green areas on the sides of the road or in median strips increase the amenity value of the trip and reduce speed and driver stress and fatigue. In contrast, clutter is perceived negatively and distracts and disorients drivers. Clutter is caused by the presence of an excessive number of elements (e.g., traffic signs, billboards) with different sizes, shapes, and colors, and placed at different positions, some at eye level, and others overhead.

Road lighting has both negative and positive effects on drivers. Overly bright road lighting or glare from other vehicles’ headlights at night distract the driver and pose safety risks, but also increase visibility of the road and other vehicles, addressing not only traffic safety but also personal security.

Car users may respond to visual impacts by changing their routes, avoiding the less attractive ones. They may even change their travel destinations to avoid unattractive places or the routes to access them. These behaviors are common for leisure trips, but for commuting or shopping trips are often unfeasible, because alternative routes may be longer or more congested. There is little empirical evidence on how car users trade-off the visual quality of different routes against trip length, duration, and cost.

The view that car users have from the road also has consequences on health and well-being. Regular exposure to unattractive views contributes to commuter stress, lower satisfaction with one’s residential and work areas, and lower subjective well-being. In contrast, exposure to nature-dominated drives may contribute to stress recovery and immunization.

Most of the methods for visual impact assessment mentioned in the first part of this article also apply to the case of car users, with some differences. For example, viewsheds represent what can be seen from the infrastructure. Official guidance on how to use the assessment methods, and on the range of aspects to consider, tends to be more detailed than in the case of impacts on non-users.

Figure 6 Example of road landscaping (Lima, Peru).

Guidelines mention both objective aspects (e.g., visibility, quality, maintenance of materials) and subjective aspects (e.g., harmony, character).

Visual aspects can become an important factor determining road alignment and design. This is especially the case of roads in areas with natural or cultural interest. There are programs in several countries that frame the planning and management of these roads—for example the National Scenic Byways program in the United States and the National Scenic Routes program in Norway.

The visual experience of car users can also be improved with small, but effective measures, even in busy roads in urban areas. Common interventions include adding, improving, or simply maintaining landscaped areas, and using more a visually appealing road pavement (Fig. 6). In some countries, fountains or public art have also been placed on roundabouts.

There are also regulations to reduce clutter, both in large infrastructure and in urban roads and streets. In the United States, the Highway Beautification Act of 1965 was one of the first laws aimed at improving the appearance of roads and the views from it, by regulating the number and characteristics of signs and billboards, as well as some unsightly land uses that can be seen from the road. In São Paulo (Brazil), the Lei Cidade Limpa (“Clean City Law”) outlawed the use of outdoor advertisements. Again showing the subjectivity of visual impacts, both of these examples have attracted controversy not only from the businesses that had placed the billboards but also from some road users who liked to see them.

Introduction

Although it is generally realized that the use of roadway lighting can contribute to reduced crashes and an improved sense of safety and security at night, there is also an increasing awareness among public authorities that outdoor lighting along roadways and other facilities can have negative impacts collectively referred to as light pollution (Riegel, 1973). Although this chapter focuses on those impacts as they affect human activity and observation, the potential effects of lighting on wildlife including insects and nocturnal animals are also beginning to be understood (Longcore and Rich, 2004).

This chapter is organized according to the three main light pollution impacts that have been studied:

- Sky glow
- Light trespass
- Glare

Within each of the sections of this chapter that address these aspects of light pollution, the relative impacts of the quantity, the spectral distribution, and the spatial distribution are discussed, followed by several simple recommendations for the design and specification of roadway lighting systems that can help to mitigate light pollution. Finally, a simple photometric system for quantifying light pollution impacts and comparing alternative lighting systems is described.

Sky Glow

Sky glow refers to the brightening of the nighttime sky caused by electric light sources present in the outdoor environment. Before the widespread application of roadway and other forms of outdoor lighting, the Milky Way galaxy was visible in the night sky throughout most, if not all, of the world, at least, on clear nights. This section discusses lighting related factors that influence sky glow.

Quantity of Light

Probably the most important factor related to sky glow is the amount of light (e.g., illuminance on the ground or luminance of the paved roadway surface) used in the specific lighting application. It has been understood for several decades (Waldram, 1972) that light reflected from the illuminated ground surfaces provides the majority of the contribution to increased sky luminance. This can

Figure 1 The average illuminance on an enclosure around a lighted road or parking lot is about one tenth of the average illuminance on the ground surface.

be critical because many recommended practices for roadway and outdoor illumination (CIE, 2010; IES, 2018) throughout the world are expressed in terms of the *minimum* recommended value for the average illuminance or luminance.

Only very recently have such guidelines begun to discuss the notion of not exceeding these minimum recommendations by a substantial amount. Indeed “ratcheting” light levels on roads in order to allay perceived concerns about security has resulted in a substantial number of overlighted roads and parking lots, with a direct impact on the amount of light reflected into the night sky. Figure 1 illustrates that the total amount of light coming from an outdoor lighting installation along a roadway or parking lot is proportional to the amount of light falling on the pavement. The average illuminance on an enclosure around a lighted road or parking lot (representing light that can contribute to sky glow) is about one tenth the average illuminance on the horizontal surface, which matches the average reflectance of asphalt pavement of about 10% (Brons et al., 2008).

Spectral Distribution

Recently there have been calls among the astronomical observation community to limit the short-wavelength (“blue”) output of outdoor lighting in order to help minimize sky glow impacts. The basis for these recommendations is Rayleigh scattering, which is proportional to the reciprocal of the fourth power of the wavelength of light. Rayleigh scattering occurs when the size of the scattering particles is similar to the wavelength of the light being scattered (for visible light, this is 400–700 nm). The majority of atmospheric light scatter that contributes to sky glow is caused by aerosols, which contain particles that are typically an order of magnitude larger than the wavelengths of light. Scattering from aerosols is a different type of scatter known as Mie scattering, which is much less sensitive to the wavelength of the scattering light. As a consequence, light from all visible wavelengths is scattered to a similar extent and the spectrum has a relatively small impact.

Bierman (2012) and Rea and Bierman (2015) calculated the impacts of changing the spectral distribution of outdoor lighting from a yellowish light source (high pressure sodium, HPS) with a correlated color temperature (CCT) of 2200 K to a cool-white light emitting diode (LED) light source with a CCT of 6500 K. The relative amount of scattered light depended in part on the aerosol content of the atmosphere (spectral differences were greater for dry, clear air relative to humid air) but were no larger than 10%–20%. Of interest, the perceived brightness from light with a higher CCT (Rea et al., 2011) could allow the light level from an LED source to be reduced relative to HPS, while still maintaining an equal or greater perception of brightness. Such a reduction would have a corresponding reduction in the amount of sky glow.

Near astronomical observatories, where the ability to detect faint celestial objects is critical, the use of low pressure sodium (LPS) sources for road lighting is often encouraged. LPS lamps emit nearly monochromatic light at a wavelength of 589 nm, appearing deep yellow in color. Filters are available that block this wavelength while allowing others to pass through, permitting astronomers a largely unimpeded view of the night sky.

Spatial Distribution

The spatial distribution can have obvious effects on sky glow; if a streetlight used for roadway lighting emits light in the upward direction toward the sky, most if not all of that light will contribute to sky glow. For this reason, roadway lighting recommendations (IES, 2011) have tended to promote the use of “fully shielded” fixtures that emit no upward light. Fortunately, even “cobrahead” style lights with a drop lens emit relatively little upward light even though a portion of the lens is visible from above the fixture. Typically, the amount of luminous flux from a roadway lighting fixture that goes upward is no more than about 0.5% of the total flux from the fixture. Relative to the amount of light reflected from illuminated surfaces, this direct contribution is small. The same cannot be said for “globe” style and some other decorative types of streetlighting fixtures, which emit a large amount of light in the upward direction (up to 50% for globe fixtures).

Recommendations for Minimizing Sky Glow

The following steps can help minimize sky glow from roadway lighting:

- Use light levels that are no higher than needed for the type of road being illuminated.
- Avoid installing fixtures that produce upward light.
- Near astronomical observatories, consider using LPS lighting systems.

Light Trespass

The phenomenon of light trespass occurs when light from a roadway lighting installation or other outdoor location is incident on nearby properties. This can be especially bothersome when light enters the windows of residences at night. This section addresses how different aspects of lighting can influence the perception of light trespass from roadway and other outdoor lighting.

Quantity of Light

Obviously, a lighting installation that casts much of its light onto adjacent properties rather than onto the location of interest (e.g., the road right-of-way) will potentially increase the likelihood of that installation producing light trespass. Some recommendations for preventing light trespass have stipulated upper limits for the illuminance that can fall onto the windows of nearby properties. These limits (CIE, 2003) can range from 1 to 25 lux depending upon the time of night (lower illuminances for postcurfew periods and higher for precurfew) and the type of location (lower for rural locations, and higher limits for urban locations). Adaptive roadway lighting that reduces light levels during hours when fewer vehicles and pedestrians are using the road, and when residents are more likely to be sleeping, can also be considered as a strategy for reducing light trespass.

Spectral Distribution

As described in the previous section of this chapter regarding the spectral distribution of light as it pertains to sky glow, the brightness appearance of a lighted space is influenced by the amount of short-wavelength (“blue”) light produced by the light source. Thus, it is possible that a roadway lighting fixture that produces light with a high CCT (cool-white appearance) would make an interior space look brighter than one with a lower CCT (warm-white appearance) even if the measured amount of light reaching a window from outside were the same. Nonetheless, this would be a relatively small impact compared to the quantity of light.

Spatial Distribution

In order to cast light onto the windows of adjacent residential properties, light from roadway fixtures needs to be emitted at relatively high angles from directly below the fixture. However, it should also be noted that the illuminance on a surface from a light source is inversely proportional to the square of the distance between the source and the surface. **Figure 2** illustrates the maximum vertical illuminance from an outdoor lighting installation for different distances from the property line. Right along the property line the maximum vertical illuminance is nearly 200 lux, higher than many light levels in residences during the daytime, and greater than any recommended maximum level for light trespass (CIE, 2003).

As the distance from the property line increases, however, the maximum vertical illuminance decreases sharply so that for a distance of 20 m from the property line the illuminance is only 1.5 lux. This illustrates the strong influence the location of streetlight poles as well as of windows can have on light trespass. In an urban area, building facades are often located very close to the street while in rural locations the building may be set far back from the street; each of these will have very different amounts of light potentially entering windows. Another

Figure 2 Maximum vertical illuminances from an outdoor lighting installation, as a function of the distance from the property line.

Figure 3 Ratings of discomfort glare on the *de Boer* (1967) scale (9 = just noticeable glare, 7 = satisfactory, 5 = just acceptable, 3 = disturbing, and 1 = unbearable) under nighttime conditions as a function of the illuminance at the eyes from a glare source.

mitigating factor for light trespass can be the installation of house-side shields on streetlighting fixtures to block light that could reach residential windows.

Recommendations for Minimizing Light Trespass

In order to minimize the potential for roadway lighting installations to contribute to light trespass, consider the following:

- Locate streetlight poles as far from adjacent properties as practical.
- Use adaptive lighting strategies to reduce light levels during late hours of the night.
- Use house-side shields to reduce the amount of light that can enter windows from streetlights.

Glare

Glare can be defined in two ways: one is the reduction in visibility from a bright light source caused by scattered light within the eyes, and another is the sensation of discomfort, annoyance or even pain created by a light that is much brighter than its surrounding environment. Roadway lighting can contribute to both types of glare because streetlights are by nature, bright points of light viewed during otherwise dark conditions. This section discusses how different aspects of lighting influence perceptions of glare.

Quantity of Light

At night, the intensity of a light source plays a major role in the degree to which that light source can create glare, as illustrated in [Figure 3](#). A secondary factor is the background light level; when a roadway is illuminated to a higher luminance, this actually reduces the impacts of glare because the contrast between the light source and the surrounding area is lower. This is why vehicle headlights are often judged as glaring at night, but when viewed under daytime conditions do not create any discomfort at all. The [IES \(2018\)](#) states that part of the reason for roadway lighting is in fact to reduce the effects of discomfort glare.

Spectral Distribution

Similar to the perception of brightness of a lighted scene, two bright light sources that have the same intensity but different spectral distributions will not necessarily be judged as equally uncomfortable. A source that produces more short-wavelength output (or has a higher CCT) will tend to elicit more discomfort than one that is dominated by longer visible wavelengths ([Bullough, 2009](#)).

Spatial Distribution

When roadway lighting began to be used widely on streets, a “cutoff” classification system was developed to define the maximum intensity at high angles from directly below a streetlighting fixture. Noncutoff streetlights had the highest maximum intensities; semi-cutoff streetlights intermediate values, and cutoff streetlights produced the lowest high-angle intensities, and as a consequence, cutoff luminaires tended to produce the least amount of discomfort glare. This system was used with success for many decades ([Bullough, 2002](#)) until it was replaced with a similar system ([IES, 2011](#)) that also addresses upward light from a street lighting fixture. Discomfort and disability glare are both also reduced when the distance between the glare source and the line of sight is increased. For this reason, streetlight fixtures should only be mounted on poles that are less than 5 m in height when the wattage of the lights is low.

Figure 4 Virtual “box” enclosure used in the OSP system.

Recommendations for Minimizing Glare

In order to reduce the potential for roadway and other outdoor lighting installations to create glare, consider the following:

- Minimize high-angle intensity from the streetlight fixtures.
- Use lower CCTs when feasible as a secondary option.
- Mount bright streetlights higher than 5 m from the ground to maximize the angle between the streetlight and drivers’ or pedestrians’ line of sight.

Outdoor Site-Lighting Performance System

In order to compare lighting configurations in terms of light pollution impacts including the potential to produce sky glow, light trespass or glare, the outdoor site-lighting performance (OSP) system was developed (Brons et al., 2008). The basis for this system is a virtual ‘box’ enclosure around a lighted roadway or parking lot (Figure 4) that represents the boundary between a lighted location and the exterior parts of the environment that can be affected by streetlighting or other outdoor lighting.

Using the OSP system (Brons et al., 2008), the potential for sky glow is quantified by estimating the average illuminance on the upper surface and the tops of the side surfaces of the box leaving the lighted area. The potential for light trespass is quantified by estimating the maximum illuminance on the side surfaces leaving the lighted area. Glare is quantified using the illuminance from the lighting fixtures as well as the illuminance from the surrounding surfaces and the ambient environment (Bullough et al., 2008), at a height of 1.5 m along the side surfaces of the box. The OSP system is used in recommended practices for outdoor lighting at airports as a way to quantify and compare the potential to create light pollution (IES, 2015).

Introduction

Roads, highways, and railroads are components of transportation infrastructure that are essential to functioning societies. Dense networks of roads generally occur where residential, commercial, and industrial development is most concentrated. Railroads and highways typically stretch out over long expanses of land, connecting people of different counties, parishes, states, provinces, and countries. Many of the environmental impacts of roads and railroad, and the vehicles that travel on them, are well known. Air, water, and noise pollution, the contamination of soil and vegetation, as well as automobile accidents are unavoidable consequences of maintaining elaborate networks of transportation infrastructure. While impacts to environmental quality, human health, and safety are well integrated into transportation policy, planning, and regulation, another environmental consequence of extensive transportation networks—the effects of roads, highways, and railroads on fish and wildlife populations—receives far less attention.

The effects of roads, highways, and railroads (transportation infrastructure) are most obvious when animal–vehicle collisions cause property damage, injury, or death, or by the presence of road-killed animals along roads and highways. Wildlife mortality caused by vehicle collisions is an important factor affecting the persistence of wildlife populations, but the impact of transportation infrastructure includes other elements that negatively affect wildlife populations. These include habitat loss and degradation, as well as the barrier effects of roads, highways, and railroads.

The ecological road-effect zone, the area of adjacent land that is ecologically affected by a road or highway, is variable in width depending on the size and characteristics of the roadway but averages around 600 m (Forman and Deblinger, 1999). There are approximately 64 million km of paved and unpaved roads on earth (CIA) and it is estimated that 83% of the continental United States is located within 1 km of a road or highway (Ritters and Wickham, 2003). The amount of new transportation infrastructure is growing rapidly in the developing world, and although the pace of new road construction has slowed in the developed world, existing roads/highways are being widened and traffic volumes are increasing. Collectively, the roads, highways, and railroads around the globe have had an enormous impact on fish, wildlife, and ecosystems. To conserve the Earth's biodiversity resources we must consider how we might reduce these impacts both for existing transportation infrastructure and for new roads, highways, and railroad yet to be constructed.

This chapter focuses on the impact of transportation infrastructure on fish and wildlife populations, and what we can do to avoid, minimize, or mitigate those impacts. Much of the research on this subject has examined the effects of roads and highways; thus, much of the chapter will focus on those impacts. However, the effects of railroads on wildlife populations are quite similar, and many of the concepts and examples described for roads and highways are just as relevant for railroads.

Impacts of Roads and Railroads on Fish and Wildlife

Effects on Habitat

Roads, highways, and railroads are poor habitat for most fish and wildlife. Wherever these elements of transportation infrastructure replace natural areas there is a direct loss of habitat. The amount of available habitat can be further reduced if wildlife avoid natural

areas associated with roads, highways, and railroads because of light, noise, edge effects, or the commotion caused by vehicular traffic. Wetland and aquatic habitats are degraded by changes in hydrology, water quality, water temperature, and loss of outside inputs such as leaf litter and woody debris. Degraded habitat may be able to sustain fewer individuals of a given species or may be rendered completely unsuitable as habitat.

Habitat fragmentation occurs when areas of contiguous habitat (e.g., forest) is dissected by transportation infrastructure, creating smaller patches of that habitat type, more edges (e.g., where forest abuts more open habitats such as grasslands or shrublands), and less core area (areas insulated from edges). Some wildlife species are edge sensitive, meaning that their survival or reproduction is reduced by edge predators, brood parasites (e.g., brown-headed cowbirds, *Molothrus ater*, in North America that deposit their eggs in other birds' nests), and changes in microclimate that are unfavorable for the species. As patches of habitat become smaller and more isolated, they support smaller populations of fish or wildlife. Some species are so vulnerable to edge effects that they are considered area-sensitive, meaning that they will not nest in habitat patches below a certain size.

Another aspect of roads and highways that can affect the amount and quality of habitat available to fish and wildlife is the secondary impacts of road building. Where roads go people and development usually follow. Road building facilitates development and extractive industries that can result in habitat loss and degradation that extends farther out from the road footprint and well into the future.

Any reduction in available habitat, due to habitat destruction or wildlife avoidance of areas near transportation infrastructure, reduces the fish and wildlife carrying capacity of the area. Smaller and more isolated populations are more vulnerable to the adverse effects of random (stochastic) events. These include environmental stochasticity, such as atypical weather conditions (unusually rainy or dry years, severe winters), or changes in the abundance of food, shelter, predators, competitors, parasites, and diseases. Very small populations are also vulnerable to demographic instability and genetic changes due to random chance. The smaller a population, the more susceptible it is to random or unusual events and the less likely that it will persist well into the future.

Road Mortality

An obvious impact of transportation infrastructure is the loss of individual animals to roadkill. Road mortality rates tend to be highest right after the roadway is opened to traffic and decreases over time as wildlife populations are diminished or eliminated. One study conducted in western France a year after a new motorway opened documented 2266 road-killed vertebrates representing 97 species over the course of 33 weeks (Lodé, 2000).

The impact of road mortality on wildlife populations may range from severe to negligible, even if the numbers killed on the road are high. It is not the absolute number of individuals killed that matters. It is whether the road mortality is compensatory or additive. For some species, human-caused mortality (roadkill or hunting) may have a minimal effect on populations if the individuals killed are likely to have died anyway, due to predation or winter mortality. For example, many species of frogs and toads produce large year classes of young that experience high rates of natural mortality. This is true for many prey species with high reproductive rates, such as rodents and rabbits. Furthermore, some species can compensate for elevated mortality rates through increased reproduction, becoming reproductive at an earlier age, or via immigration from surrounding areas.

At the other end of the spectrum are species for which any human-caused mortality is likely to be in addition to, rather than in place of, natural mortality. This typically occurs in species that have naturally low reproductive rates and relatively long life spans. Large carnivores, such as grizzly/brown bears, *Ursus arctos*, and wolverines, *Gulo gulo*, typically fall within this group. Road mortality has been identified as an important threat affecting endangered species/subspecies such as the Florida Panther, *Felis concolor coryi* (Maehr et al., 1991), Old World badger, *Meles meles* (van der Zee et al., 1992), and Iberian lynx, *Felis pardina* (Ferrerias et al., 1992). Turtles and tortoises are particularly vulnerable to population decline due to road mortality (Beaudry et al., 2008). These animals are generally characterized by low reproductive rates and high adult survival rates (in excess of 100 years for some species). Adult longevity makes up for low reproductive potential. Slow moving and often attracted to road shoulders for nesting, turtles and tortoises are vulnerable to vehicle strikes, and road mortality is usually additive, killing animals that are unlikely to die otherwise. Due to their low reproductive rates, they have very little capacity to compensate for the added adult mortality.

Transportation infrastructure can also increase wildlife mortality by serving as attractive nuisances. Grassy roadside verges can attract grazing animals, putting them in close proximity to vehicular traffic. Ungulates and North American porcupines, *Erethizon dorsatum*, in need of sodium will seek out road and highway shoulders for road salt. Spilt grain along roadsides or railroad tracks can attract and concentrate wildlife, creating opportunities for roadkill. Storm water management systems can attract amphibians to busy roadsides in order to breed or forage in artificial basins, which may not hold water long enough for deposited eggs to hatch and for larvae to develop and transform into juveniles.

Roads and highways also indirectly increase wildlife mortality by facilitating human access to areas that would be otherwise difficult to reach. Wildlife mortality due to hunting, poaching, or extractive industries, only adds to the direct toll taken by the roads, highways, and railroads themselves.

Barrier Effects of Transportation Infrastructure

Importance of Animal Movement

Movement is critically important to the survival of individual animals and the persistence of fish and wildlife populations. Even relatively sedentary species, such as freshwater mussels, have a dispersal life stage that facilitates genetic mixing and colonization of

vacant habitat. In North America, freshwater mussels produce parasitic microscopic larvae called glochidia that are released into water. These glochidia attach to gills or fins of particular species of fish (or aquatic salamanders) where they will complete their larval development and eventually drop off and, if they land in an area of suitable habitat, will continue their lives as juveniles, then adult mussels. The persistence of mussel populations is dependent on the presence of suitable fish hosts and an environment that allows those fish to move within their aquatic habitats (streams, rivers, lakes, and ponds).

Individual animals move within and between areas of suitable habitat for a variety of reasons. Some are routine daily movements to forage or seek shelter from predators or the elements. Animals move to access vital habitats such as breeding habitat, mineral licks (salt licks), and thermal refuges (especially important for cold-water fish). Some species migrate long distances between summer and winter habitat. Some are movements tied to reproduction, as individuals seek mates or suitable nesting, denning, or spawning habitat.

Many amphibian species undergo seasonal migrations from terrestrial overwintering habitat to aquatic breeding sites in the spring. Although many turtles are aquatic or semi-aquatic, all but a few species must lay their eggs on land. These nesting movements present a number of hazards (including roads) to adult female turtles. In order to mature and complete their life cycles, juvenile amphibians and hatchling turtles must complete these movements between aquatic and terrestrial habitats in reverse. Breeding movements may involve long-distance travel, such as when anadromous fish like salmon, river herring, and sturgeon migrate from the ocean up into freshwater streams and rivers to spawn. Eels are catadromous fish whose adults migrate from freshwater to the ocean and the juvenile life stages migrate back upstream to complete their development in freshwater habitats.

Another reason why movement is so important for fish and wildlife is that habitat conditions change. Some of that change is natural and expected such as when vegetative communities change due to natural succession, or when the arrangement of sediment and woody debris in streams shifts in response to seasonal high flows, causing changes in the distribution of riffles, pools, or runs. In other cases, change may be sudden and unexpected, such as fire, floods, droughts, or severe storms. The change in conditions may be short term or long term, but individual animals often need to relocate to areas with more favorable conditions.

Movement is also important at the population level. Populations are groups of individual animals that regularly interact and interbreed. As discussed above, movement is essential for reproduction and the routine interactions among individuals that make up populations. Constraints on movement often delineate one population from another, each population distinguished by demographic characteristics (birth, death, immigration, and emigration rates) that are independent from other populations. Animal movements help maintain the continuity of populations and barriers to movement can fragment populations, producing smaller populations with reduced long-term viability. Dispersal of individuals away from populations is important for regulating population density and maintaining abundance levels within the carrying capacity of their environment.

Despite their inherent vulnerability to environmental, demographic, and genetic stochasticity, small populations of fish and wildlife can persist for long periods of time when they are part of a network of local populations linked together via occasional movements of individuals between and among those populations. These networks of populations, otherwise known as regional populations or metapopulations, are very important for the long-term maintenance of local populations.

Within regional populations, the movement of individuals between local populations is rare enough that the local populations remain distinct from each other, but occurs often enough that it helps maintain the regional population over time. Dispersing individuals from neighboring populations may provide immigrants that supplement the local population and help it maintain population levels even when local reproduction is insufficient to do so on its own. Occasional movement of individuals between and among populations can provide an infusion of genes (gene flow) that can partially or entirely negate the genetic deterioration that often results from small population size. When local populations do fail, the movement of individuals from other nearby populations provides a source of colonizers that can reestablish populations in habitat where local extinctions have occurred. A balance between local extinctions and recolonizations can maintain networks of local populations far longer than isolated populations could persist in the absence of such population level exchanges.

Roads, Highways, and Railroads as Barriers

Mortality is a significant barrier associated with transportation infrastructure. Animals killed on the road fail in their attempts to cross roads, highways, or railroads. However, the barrier effects of transportation infrastructure go well beyond that. These additional factors generally fall into two categories: physical barriers and behavioral barriers.

Fish and other aquatic organisms are likely to encounter various barriers associated with road-stream crossings. Most, but not all, bridges provide good aquatic organism passage. Culverts, on the other hand, rarely provide full passage for all aquatic organisms that inhabit those streams. Because culverts usually do not span the entire width of the stream, they concentrate flows and result in velocities that are higher than would normally be encountered in the natural stream channel. Fish and other aquatic organisms that cannot swim faster than the velocity of the water are presented with a velocity barrier that can delay or completely obstruct upstream passage. Some species that can manage to swim faster than the current often cannot keep up the effort long enough to make it through the culvert (exhaustion barrier). Concentrated flows create more erosive power and often create scour pools at the outlet that leave the bottom of the culvert perched above the water surface in the receiving pool below. Some fish, such as some species of salmon and trout, are excellent jumpers and may be able to overcome sizeable outlet drops. However, many fish cannot jump at all or are weak jumpers, and these outlet drops represent significant obstacles (jump barriers) to passage. Undersized culverts will typically back water up at the inlet which can result in turbulence that can disorient fish (turbulence barrier) and the accumulation of substrate at the inlet resulting in inlet drops.

Fish often encounter multiple barriers when trying to pass through culverts. It is possible that a fish traveling upstream to spawn, or up into a small tributary to escape warm summer water temperatures, could encounter an outlet drop requiring a jump to get into the culvert, a velocity or exhaustion barrier, and end with a second jump barrier to exit the culvert over an inlet drop. For fish, or other aquatic organisms that can swim but cannot jump, they will be blocked at the outlet without even getting into the culvert.

For terrestrial wildlife, physical barriers include the surface of roads and highways, as well as the rails and ballast of railroads. Although railroad tracks hardly seem like insurmountable barriers to movement, turtles find it difficult to cross over the tracks and have sometimes been trapped between the rails. The ballast stones used along some rail lines generally contrast with the substrate of nearby areas. Animals, such as moles, that travel below ground would presumably find it difficult to cross railroad tracks atop ballast stone. Similarly, wide sections of paved road or highway would present a significant physical obstacle to moles and other burrowing animals.

There are other features of roads and highways that serve as barriers to wildlife passage. These include Jersey barriers, retaining walls, noise barriers, steep embankments, deep road cuts, and right-of-way fencing. On smaller roads, something as simple as traditional curbing, when combined with catch basins, can serve as traps for salamanders and small (e.g., hatchling) turtles. When encountering curbs, these animals seek a route around the barrier. As they walk along the curb and encounter a catch basin they often fall into and are trapped in the deep sumps of these basins.

Behavior barriers occur when characteristics of the road, highway or railroad, present conditions that are risky for wildlife to cross. Some wildlife avoid roadsides because of the noise, light and/or activity of vehicular traffic. Others are reluctant to expose themselves to predators by crossing areas that are essentially devoid of cover. Studies have documented that several species of small mammals are reluctant to cross even relatively small roads (Oxley et al., 1974; Mader, 1984; Swihart and Slade, 1984). Although some arboreal wildlife (species that spend most of their lives in tree canopies) will move across the ground and might be willing to cross over a road surface, other species generally stick to the trees and are very reluctant to travel on the ground. The wider the expanse of road the stronger the deterrent to passage. It is not hard to image that few animals will successfully cross a six or eight lane superhighway, most won't even try.

Impacts of Increased Mortality and Reduced Wildlife Passage

When considering the impacts of transportation infrastructure, it is important not to get too focused on impacts to individual animals, but to focus instead on the long-term impacts on fish and wildlife populations. The ability of populations to persist over time is a function of demographic rates (birth, death, immigration, emigration) which, in turn, are determined by demographic characteristics (abundance, spatial distribution, sex ratio, age structure, genetic structure) of those populations. To the extent that road mortality and the loss of connectivity affects these demographic rates and characteristics, they can affect population growth rates, and may push populations into steep or gradual declines. Here is a summary of the effects of roads, highways, and railroads on fish and wildlife populations.

- Roadkill leading to the loss of populations
- Reduced access to vital habitats or habitat features (breeding habitat, overwintering areas, thermal refuges, mineral licks, etc.)
- Reduced ability to relocate in response to changing habitat conditions
- Fragmentation of populations, creating smaller more isolated populations that are vulnerable to demographic and environmental stochasticity, catastrophes (fire, flooding, drought, etc.), and the loss of genetic variability due to genetic drift and inbreeding depression
- Disruption of processes (supplementation, gene flow, and recolonization) that maintain regional populations over time

Following are some examples of how roads, highways, and railroads negatively affect fish and wildlife populations.

Research on seven salmonid fish in western North America found that the percentage of areas with healthy populations was 58% in roadless watersheds but declined to 16% for watersheds with road densities exceeding 4 km/km². In a study of Agassiz's desert tortoise (*Gopherus agassizii*), Nafus et al., 2013 concluded that roads may decrease tortoise populations via cumulative mortality and reduced population growth rates due to the loss of reproductive adults. Steen and Gibbs, 2004 and Aresco, 2005 observed turtle populations that had sex ratios that were dramatically biased toward males, and attributed it to the effects of road mortality on nesting females.

Sawaya et al., 2019 documented demographic fragmentation of a wolverine population bisected by a major transportation corridor and concluded that sex-biased impacts on dispersal (females rarely crossed the highway) led to genetic isolation. Similar sex-biased impacts were documented for grizzly bears, *Ursus arctos horribilis* (Proctor et al., 2005). The authors of this study concluded that although movement of male bears across the highway was sufficient to mediate concerns about genetic connectivity, disruption of female dispersal would reduce the possibility for supplementation and re-colonization.

An early example of the impact of transportation infrastructure on population genetics was documented by Reh and Seitz, 1990. They found significant genetic differences in a population of common frog, *Rana temporaria*, that was surrounded by roads, a highway, and a railway, and presumably isolated from other populations of that species. Since then, many studies have documented the loss of genetic diversity due to road mortality and the loss of connectivity as well as genetic differentiation among populations separated by highways. Epps et al., 2005 looked at genetic diversity of 27 populations of desert bighorn sheep, *Ovis canadensis nelsoni*, and discovered a rapid reduction in genetic diversity due to isolation by highways, canals and developed areas. Studying wildlife affected by a freeway in southern California (USA), Riley et al., 2006 found genetic isolation in carnivore populations despite moderate levels of dispersal across the highway. A 2010 review of genetic effects of roads and highways (Holderegger and Di

Giulio, 2010) found that roads often decrease genetic diversity of affected wildlife populations due to reduced population size, and decrease functional connectivity as indicated by increased genetic differentiation of populations.

With information about demographic rates and characteristics, and how those rates and characteristics are affected by transportation infrastructure, ecologists can use population viability modeling to estimate persistence time for populations under various scenarios. Taylor and Goldingay, 2009 estimated the probability of extinction for the greater glider, *Petauroides Volans*, for a population in a remnant area of habitat in Australia with and without a land bridge to facilitate highway crossings. Their modeling suggested that if no dispersal across the road occurs, that subpopulation of this arboreal mammal has a very high probability of extinction within the next 100 years. Persistence improves dramatically when a moderate amount of dispersal is included in the model. Ramp and Ben-Ami, 2006 modeled population viability for the swamp wallaby, *Wallabia bicolor*, and found that a 20% decrease in female roadkill deaths had the potential to stem a projected population decline and improve long-term viability for this population.

Although some population extinctions occur soon after a motorway is opened to traffic, changes in demography and population genetics typically take many years to manifest and there is likely to be a significant lag time involved in transportation-related population loss. A study in Ontario, Canada, by Findlay and Houlahan, 1997 investigated species richness for birds, reptiles, amphibians, and plants in 30 wetlands relative to surrounding land use. They found a significant relationship between species diversity and the density of paved roads within 1.9 km of the wetlands. Further analysis of the data (Findlay and Bourdages, 2000) found that the relationship between road density and species diversity was stronger when they used the road network as it existed in 1944. This suggests that lower species diversity observed today may be the result of roads, highways, and railroads built many years ago, and that impacts of transportation infrastructure are likely to continue well into the future.

Mitigating Transportation Impacts on Fish and Wildlife

There are many techniques and approaches that have been used to mitigate the impacts of roads, highways, and railroads on fish and wildlife populations. Some are primarily focused on reducing animal-vehicle collisions; others seek to both reduce road mortality and enhance connectivity across motorways and railroads. There have been numerous studies that have evaluated these various approaches and provide information about their performance for various species. However, the settings and the species differ from case to case, and it is not easy to draw general conclusions about the efficacy of mitigation techniques.

Mitigation Techniques That Don't Involve Crossing Structures

Curbs: A simple way to reduce road mortality and improve crossing success for salamanders and turtles is to avoid traditional curbing in favor of gently sloping berms or country drainage (no curbs).

Fencing: Fencing is often used to prevent large mammals from accessing motorways. They are relatively ineffective for climbing animals or those that can easily burrow under the fences. Fencing may be successful at reducing animal-vehicle collisions but they can exacerbate the barrier effects of transportation infrastructure.

Warning signs: Wildlife warning signs are widely used because they are relatively inexpensive. Motorists, however, grow accustomed to the signs and any effects on driver behavior are typically short-term. Signs that are erected and taken down seasonally have a greater chance of being successful.

Animal detection systems: Used in combination with warning signs and flashing lights, animal detection systems alert motorists when large animals have been detected in (or in close proximity to) the road ahead. In the past, these systems have proven relatively ineffective because false positive detections can lead drivers to conclude that they cannot be trusted.

Crosswalks: Fencing or habitat manipulation can be used to concentrate wildlife into designated crossing zones, or crosswalks. These crossing areas are chosen for their good visibility and are accompanied by warning signs and, occasionally, animal detection systems. While in some cases, this approach has reduced the number of animal-vehicle collisions along a stretch of road, it does create collision hot spots where concentrations of animals may be on or around the roadway.

Reflectors, mirrors, and flagging models: These techniques are typically used to keep ungulates (deer, moose, and elk) off roads and highways. Reflectors and mirrors spray light from vehicle headlights into the surrounding landscape in hopes that wildlife will be alerted to the presence of vehicles and/or spooked into leaving the roadway. Flagging models use cutouts of deer rumps with erect tails to signal alarm to approaching deer. None of these techniques has been particularly effective at preventing animal-vehicle collisions.

Chemical repellents: A handful of chemical repellents have been tried in an effort to keep wildlife away from roads, with mixed success. Some studies report positive effects; others report no effect. The same repellent can successfully repel some species while actually attracting others. When successful, chemical repellents tend to yield only modest benefits.

Forested medians: Studies of arboreal mammals in Australia have documented the positive effects of forested medians. When the width of a highway is too great for mammals to glide across, successful crossings can occur using the forested median as a stopover point (van der Ree et al., 2010). Forested medians may also serve as habitat for small mammals (a genetic reservoir) that helps maintain genetic connectivity between populations that would otherwise be completely separated on opposite sides of a highway.

Wildlife Crossing Structures

Wildlife crossing structures, built specifically to facilitate wildlife passage across roads, highways, and railroads, come in many sizes and designs. Different wildlife species often have specific requirements and there are no designs that meet the needs of all species. Small and inexpensive structures can be used more frequently to make transportation infrastructure more permeable. Larger, more

expensive structures tend to accommodate more species, but with large spaces between structures that may not serve the needs of small animals and species with limited mobility.

Structures for arboreal wildlife: Canopy bridges and glider poles have proven successful at assisting arboreal species (including gliding mammals) across roads in Australia (Soanes et al., 2015) and may have at potential for promoting connectivity for tree dwelling and gliding animals in other parts of the world.

Amphibian tunnels: Underpass systems designed and located specifically to facilitate breeding migrations of frogs, toads and salamanders have an extensive history in Europe and their use has more recently spread to other countries. Various designs have been tried with some designs proving more effective than others. Open-top structures are preferred because they allow rain to enter the tunnels and keep the substrate wet during migrations.

Upland culverts: Culverts ranging in size from 0.5 to 5.5 m in diameter have been used specifically to facilitate wildlife movement under roads, highways, and railroads. Small culverts can be effective for species of wildlife like weasels, mink, stoats, and martens, that are comfortable entering confined spaces, but are unlikely to be used by most wildlife. The larger the culvert size, the more species likely to be accommodated.

Wildlife underpasses: Wildlife underpasses are relatively large structures designed to allow passage for large wildlife (e.g., ungulates and large carnivores). They typically can accommodate a wide range of species, although some species prefer to use smaller structures.

Wildlife overpasses (ecoducts): Wildlife overpasses, also known as green bridges or ecoducts, are bridges that allow wildlife to pass over roads and highways. These are very open structures that suit the needs of species, such as gray wolves, *Canis lupus*, and grizzly bears that are wary of confined spaces. Overpasses are most effective when they are wide (>30 m) and are designed with natural substrate and vegetation; some include cover objects and ponds. These are expensive, but highly effective structures that are used by a wide variety of wildlife.

Guide fencing: With rare exceptions, wildlife crossing structures are ineffective unless accompanied by guide fencing to funnel animals to the structure entrances. Fencing can be made of a variety of materials depending on the needs of wildlife for which the structures are intended. To guide large animals to structures, rows of boulders are sometimes used instead of fencing.

Stump rows: Rows of tree stumps can providing cover for small animals, such as mice, ground squirrels, lizards, and snakes, making it more likely that these species will use large structures like underpasses and overpasses. Rock piles or other cover objects might also work, depending on the target species.

There are many factors that can affect the success of wildlife crossings structures, including location, size, light, moisture, substrate, vegetation, cover objects, guide fencing, approaches, and human activity. For more detail about structure design and performance, consult some of the materials in the Further Reading section below.

Road-Stream Crossings

As long linear ecosystems, rivers and streams stretch out over large areas of the landscape. These river and stream networks are transportation systems for water, sediment, woody debris, and organisms. Roads, highways, and railroads are linear elements of human transportation infrastructure that traverse many of these same landscapes. It is inevitable that these two systems will frequently cross. Occasionally, waterways will disrupt the human transportation system, such as when a flood causes a culvert or bridge to fail. More often, it is roads, highways, and railroads, and more specifically the culverts (and sometimes bridges) associated with road-stream crossings, that disrupt river and stream networks.

The focus of traditional culvert design is almost exclusively on hydraulics and hydrology; how to get water efficiently across the road without disruption to the transportation system. Over time, it became clear that hydraulic design approaches often result in crossings that are impassable for some or all of the aquatic organisms that inhabit streams and rivers, as well as disrupting the transport of sediment and woody debris that is important for maintaining stream habitat.

The hydraulic approach can also be used to create passable stream crossings by designing culverts that are compatible with the swimming and leaping capabilities of particular target species (usually fish). When used in this way, crossings can be designed and constructed to allow passage for some species, but they rarely accommodate all the aquatic organisms that need to move throughout the stream network. Furthermore, we lack detailed information about the swimming and leaping abilities of most species of fish and aquatic wildlife; information needed to hydraulically design aquatic passage.

Stream simulation is an alternative approach for stream crossing design that seeks to create conditions (substrate, bed features, water depth, and velocity) within the crossing structure that mimic (i.e., fall within the natural range of variability) characteristics of the natural channel. Many bridges effectively meet the objectives of stream simulation. Stream simulation crossings are either embedded culverts or open-bottom structures (arches or three-sided boxes) that are as wide, or wider, than the width of the stream. To avoid insufficient water depths at low flow, channels are either maintained or constructed within the structures to achieve water depths and velocities at a range of flows that are comparable to those found in the natural channel.

Road-stream crossings also have the potential to provide passage for semi-aquatic and terrestrial wildlife. Many wildlife species will cross roads and highways under bridges, if those structures are large enough and provide relatively dry passage along one or both banks. Small animals can take advantage of culvert crossings on intermittent streams when they are dry. Some of the best opportunities for mitigating transportation infrastructure impacts on landscape connectivity are at road-stream crossings, where some kind of structure will already be planned or in place. The ideal situation for wildlife is when the roadway or railroad crosses the entire stream or river valley with a long bridge, also known as a viaduct.

Using stream simulation design for a crossing will generally make it passable for a number of semiaquatic and terrestrial wildlife, while also maintaining aquatic organism passage. To accommodate large wildlife species (e.g., elk, moose, grizzly bears) structures will generally need to be larger than necessary simply to achieve stream simulation. However, assuming the location is suitable, it might be more feasible to increase the size of a road-stream crossing than to construct a wildlife underpass or overpass. There are also modifications to culverts and bridges that can be used to expand the number of wildlife species capable of using road-stream crossings to get across transportation infrastructure.

Expanded bridges: Bridges can be expanded to provide a dry path with appropriate substrate along one or both banks.

Wildlife benches or shelves: Existing structures (bridges or culverts) that do not provide dry passage can be modified by the addition of benches (on the bottom of the structure) or shelves (attached to the sides of structures) to provide such passage. These can be relatively low-cost solutions that will facilitate movement for a variety of smaller animals.

Vole tubes: Voles are small mammals (rodents) that often travel through shallow tunnels in soil or dense vegetation. They are most comfortable in confined spaces and generally avoid open areas. Affixing tubes to wildlife shelves can significantly improve the use of these structures by voles (Foresman, 2003).

Conclusion

Historically, conservation efforts have focused on protecting large blocks of undeveloped land, rare and endangered species habitat, and providing recreational opportunities. As our natural areas have been increasingly fragmented by extensive road networks, residential, commercial, and industrial development and associated infrastructure, maintaining or enhancing connections among natural areas is now seen as essential for protecting the long-term viability of wildlife populations and the ecological integrity of ecosystems. To protect biodiversity for future generations, we must assess the connections among our natural areas and wildlife habitats, design strategies to protect existing connectivity, and mitigate barriers to species movement.

There are many tools and approaches available to mitigate the impacts of roads, highways, and railroads on fish, wildlife, and ecosystems. These tools and approaches can be deployed in combination and at a variety of scales to ensure an interconnected landscape that can support the long-term persistence of fish and wildlife populations.

At local scales, the focus may be on threatened and endangered species, and strategies to maintain landscape connectivity for small, less vagile species. This may involve multiple small crossing structures (e.g., amphibian and reptile tunnels) and a focus on improving passability at road-stream crossings. A regional approach is needed to maintain viable populations of wide-ranging species and to ensure that metapopulation dynamics necessary to maintain regional populations remain intact. Long-term maintenance of metapopulations for wide-ranging species, and those, like large carnivores, that typically occur at low densities, will require a large, landscape-scale approach. To be successful at the regional and large landscape scales will require the use of landscape analysis and modeling, multiple tools and approaches for reducing road mortality and increasing landscape connectivity, and the cooperation of multiple stakeholders and governmental jurisdictions. Regional and landscape-scale connectivity will only become more important over time, as climate change requires wildlife to shift their geographic distributions in response to changing habitat conditions.

Finally, we do not yet have the knowledge or technology to mitigate all the negative effects of transportation infrastructure on wildlife and ecosystems. Maintaining roadless areas, and closing roads (e.g., forestry roads) to expand roadless areas, are essential strategies for ensuring the long-term persistence of highly sensitive species, such as wolverines, wolves, and grizzly bears.

Introduction

Environmental justice (EJ), transport justice (TJ), and mobility justice (MJ) all evolved with the intent to benefit the transportation disadvantaged. There are vast differences between the concepts despite the tendency among some researchers to treat them as synonymous. EJ entered mainstream US transportation planning in the mid-1990s. On the other hand, the earliest writings on TJ and MJ can be traced back to the mid-2000s, but they have gained increased attention in more recent times, especially since 2016. It is not as if the transportation disadvantaged did not get attention from transportation agencies and researchers before the emergence of the concepts of EJ, TJ, and MJ. US researchers and agencies have expressed concerns about the transportation disadvantaged at least since the 1960s, when the Civil Rights Act and the first Urban Mass Transportation Act were passed and the initial writings on spatial mismatch appeared in response to the job access problem of minority populations. After a brief introduction to the research on the transportation disadvantaged from the 1960s to the 1980s, this article discusses the circumstances in which EJ, TJ, and MJ emerged, the similarities and differences between the concepts, and the manner in which each concept relates to transportation planning. Although justice in transportation is important around the world, the general context of this article is the US because that is where the earliest of the three concepts, EJ, evolved and TJ and MJ were founded, at least partially, as a critique of US regional transportation planning practices.

Before EJ, TJ, and MJ

One of the earliest studies to use the term “transportation disadvantaged” was [Altshuler \(1969\)](#), where only the poor and people with disabilities were considered deserving of receiving public transit subsidies because of their transportation disadvantages, namely, lack of affordability for the poor and bodily limitations for the people with disabilities. In a synthesis report by the Transportation Research Board ([TRB, 1976](#)), the term was used to describe people with disabilities, people in poverty, as well as older adults. These groups were identified as transportation disadvantaged because they could not travel with as much ease as other people. Recognizing that different people used the term to describe different population groups, including the poor, racial minorities, people with disabilities, children, older adults, and women, [McGuire \(1976\)](#) vehemently argued that people should not be considered transportation disadvantaged merely because of their race or ethnicity and suggested that the term be used to describe only people in extreme poverty or extreme disability. A number of studies in the 1970s made reference to the transportation disadvantaged ([Paaswell and Recker, 1974](#); Schnell, [Falcocchio and Cantilli, 1974](#)), but unlike [McGuire \(1976\)](#), they refrained from questioning who should and who should not be considered transportation disadvantaged.

[Altshuler et al. \(1979\)](#) contended that transportation disadvantage became a serious issue because of the increasing popularity of the automobile. That is because the greater use of the automobile was accompanied by a substantial reduction of public transit service, which decreased transportation options for people who could not afford or use an automobile. Thus, it was one of the earliest studies to point the finger at the automobile as the cause of transportation disadvantage—a tradition that has continued until the present day in the domains of TJ and MJ. Today, carless households are often considered as transportation disadvantaged, and for better or worse, public transit has been viewed by many as the savior of the transportation disadvantaged.

It is important to note the social and political environment of the period in which transportation disadvantage became a concern in the United States. The first Urban Mass Transportation Act was passed in 1964, which introduced federal subsidies for public transit ([Weiner, 2008](#)). Naturally, it prompted transportation professionals and researchers to ask who should be eligible to receive transit subsidies. Much of the early literature on the transportation disadvantaged, therefore, revolved around transit subsidies. The

Civil Rights Act was passed in 1964, which prohibited discrimination based on race, color, religion, sex, or national origin. This piece of legislation would have a profound effect on transportation agencies in the following decades. Another legislation to affect transportation policies in the United States was the National Environmental Policy Act of 1969, which continues to be a cornerstone for EJ today. The next federal law to have a profound effect on the transportation disadvantaged was the Americans with Disabilities Act of 1990, which prohibited discrimination on the basis of disability in the public as well as the private sector (Weiner, 2008). The law, as amended, required public transit agencies to implement measures to make stations and vehicles accessible to all people, including people with disabilities. The law also required transit agencies to provide paratransit service to people with disabilities who could not use fixed-route transit.

A concept from pre-EJ times that had a substantial impact on the thinking of researchers in the domain of the transportation disadvantaged is spatial mismatch. The concept is often tied to Kain's (1968) seminal study that focused on difficulties in job access for minority workers because of housing market discrimination. The concept evolved over the years through the works of Holzer (1991), Ihlanfeldt and Sjoquist (1998), and many others, bringing attention to the job access problem for low-skilled, low-income, and minority workers and, at the same time, adding the dimension of space to discussions on the transportation disadvantaged. Although the concept of spatial mismatch is not only about transportation, it helped to bring attention to the transportation problems of low-income and minority populations, especially in regard to their access to suburban job locations. In a sense, the spatial mismatch concept convinced many that the role of transportation planning is not merely to improve transportation, but also to improve economic well-being of low-income and minority populations.

Environmental Justice

Environmental justice advocacy, often referred to as a movement, began in the late 1970s and the term EJ most likely was used for the first time in the early 1980s in North Carolina in a fight against the dumping of environmental waste (Bullard and Johnson, 1997; Martinez-Alier et al., 2014). Since that time, the primary concern for EJ advocates, typically belonging to grassroots organizations, has been that racial minorities and low-income populations disproportionately suffer from pollution and other adverse effects of transportation. By the late 1990s, EJ advocacy had spread throughout the US as grassroots organizations with varied interests coalesced against transit agencies and highway authorities in many cities for unfair distribution of transportation benefits and burdens. Since that time, EJ advocacy has influenced diverse types of transportation decisions, including but not limited to tolling, congestion pricing, gasoline taxation, transit routing, transit fare, noise barriers, air pollution, and bikeshare programs.

EJ gained a tremendous boost in 1994, when President Clinton signed Presidential Executive Order No. 12898, titled "Federal Action to Address Environmental Justice in Minority Populations and Low-Income Populations." EJ entered mainstream transportation planning in 1997, when the US Department of Transportation (USDOT) issued its own order (DOT Order No. 5610.2) to make transportation policy and planning consistent with the Presidential Executive Order. The foundation for EJ is provided by Title VI of the Civil Rights Act and the National Environmental Policy Act (NEPA); the first providing the non-discrimination basis and the latter providing the implementation process. Presidential Executive Order No. 13166, titled "Improving Access to Services for Persons with Limited English Proficiency," signed by President Bush in 2000, added people with limited English proficiency (LEP) as another disadvantaged group requiring special attention in transportation and other public spheres.

The Federal Highway Administration (FHWA, 2015) and the Federal Transit Administration (FTA, 2012) continue to issue circulars to assist transportation agencies to comply with the USDOT's Title VI and EJ programs. The objective of EJ program is to ensure that the adverse effects of transportation policies, programs, and actions do not disproportionately affect minority populations and low-income populations and that the benefits and burdens of transportation are equitably distributed among all people. The Title VI program, consisting of both Title VI and EJ components, is concerned about non-discrimination on the basis of race, color, national origin, sex, age, disability, low-income, and limited English proficiency.

The USDOT (FHWA, 2015, p.11) defines minority and low-income population in the EJ context "as any readily identifiable group of minority and/or low-income persons who live in geographic proximity, and, if circumstances warrant, geographically dispersed/transient persons of those groups (such as migrant workers, homeless persons, or Native Americans) who will be similarly affected by a proposed FHWA/DOT program, policy, or activity." The terms "underserved population" and "traditionally underserved population" are often used to describe low-income and minority populations, but other transportation disadvantaged populations, such as children, older adults, and persons with disabilities are also considered underserved. Thus, underserved populations today are fairly similar to the transportation disadvantaged before EJ entered the transportation lexicon.

In the United States, metropolitan planning organizations (MPO) are entrusted with preparing regional transportation plans (FHWA/FTA, 2004). Regional transportation planning is a continuous process, beginning with the setting of regional goals and visions, followed by needs assessment, strategy identification, strategy evaluation, development of the plan document, development of the transportation improvement program, project development, and system operation/maintenance. EJ enters the planning process at many levels; while it is an essential part of public involvement and the NEPA process, many MPOs also undertake sophisticated data analysis to identify low-income and minority communities to ensure that the benefits and burdens of transportation programs and projects are equitably distributed. As MPOs typically work under resource constraints, the attention received by EJ varies from agency to agency. While some MPOs may make substantial efforts to go above and beyond what is required by laws and regulations, others can afford to make only the bare minimum effort to comply with the laws and regulations. EJ remains somewhat ad hoc in the regional planning process mainly because capabilities of MPOs vary substantially.

Thus, EJ is a concept that emerged in the late 1970s and early 1980s through grassroots advocacy that led to many successes, including new federal policies. After the EJ Executive Order was signed in 1994, EJ has become a formal part of transportation planning in the US. Unlike the concepts to be discussed in the following sections, EJ has a regulatory framework within which MPOs perform their activities. In contrast, TJ and MJ, at this time at least, are merely interesting and insightful concepts.

Transport Justice (TJ)

The term transport justice was popularized primarily by the book “Transport Justice: Designing Fair Transportation Systems” (Martens, 2017), but its normative approach can be traced back to earlier works of Martens and his peers (Martens, 2006; Martens, 2012; Martens et al., 2012). Although some authors (e.g., Beiler and Mohammed, 2016) have treated concepts of EJ and TJ as interchangeable, they are perhaps more dissimilar than similar when one enters the domain of justice in transportation.

The concept of TJ emerged as a critique of conventional transportation planning, especially in the United States, where regional transportation models are used to predict the impact of population and employment growth on network traffic and recommendations for improvement are made on the basis of the model results. The TJ proponents argue that this “predict-and-provide” practice, in the US and elsewhere, disproportionately benefits car users because more car use generates more congestion and more congestion leads to more highway investments benefiting only those who can afford to use cars. This practice benefits people who travel more by car and adversely affects people who cannot afford cars or travel less by cars. Another criticism of conventional transportation planning from the proponents of TJ focuses on the use of cost-benefit analysis (CBA) to make transportation investment decisions. They argue that the use of travelers’ income as an input in CBA unduly favors the wealthy.

In contrast to EJ, which evolved in the sphere of grassroots advocacy in the real world, the concept of TJ emerged as a justice-theoretic approach and to this day it has remained mostly theoretical. The proponents draw primarily from the writings of three social thinkers of the 20th century: Rawls (1971), Walzer (1983), and Dworkin (1981a, 1981b). On the basis of Rawls’s decision making under the veil of ignorance, the proponents argue that prudent people would agree to the distribution of social goods that maximize the welfare of the worst-off in transportation (i.e., the maximin principle). On the basis of Walzer, the proponents claim that transportation can be considered an independent sphere of social good. Using Dworkin’s insurance schemes against “option luck” and “brute luck,” the TJ proponents argue that society would prefer a distribution system that guarantees a sufficient level of social goods to everyone despite there being wide variations in welfare among people. Putting together all of the above, the TJ proponents suggest that there are two domains for the distribution of the transportation good: the domain of free exchange and the domain of justice. TJ is about the latter.

TJ is concerned about the distribution of only two social goods: potential mobility and accessibility. In contrast to revealed mobility, which reflects a person’s actual travel, potential mobility reflects the capacity to travel. In contrast to revealed accessibility, potential accessibility refers to a person’s capacity to participate in activities distributed over space rather than actual participation in activities. Thus, both concepts are based on capacity rather than the actual acts of travel and activity participation. According to the TJ proponents, accessibility is a more meaningful measure of the transportation good compared to potential mobility because mobility does not capture variations in the distribution of activities over space. Equating both potential mobility and accessibility to freedom of choice, TJ proponents hold that “ultimately accessibility best reflects the social meaning of the transport good in Western societies” (Martens, 2017, p. 53). In this regard, TJ conforms to the general acceptance among today’s planners and researchers that both land use and transportation are important rather than transportation alone.

Despite the mostly theoretical approach of the TJ concept, Martens (2017, p. 174) proposed a 10-step transportation planning model that should be of interest to both transportation planners and researchers. The sequential steps are:

1. Identify population groups by residential location, mode availability, and socioeconomic status
2. Assess their potential mobility and accessibility by multiple measures
3. Identify potential mobility and accessibility sufficiency thresholds through a democratic process
4. Identify population groups with insufficient potential mobility and accessibility
5. Assess the severity of accessibility insufficiencies for population groups by using an Accessibility Fairness Index
6. Rank population groups according to their contribution to overall accessibility deficiency
7. Identify the causes of the accessibility deficiencies for different population groups
8. Identify promising interventions for reducing accessibility deficiencies
9. Assess the effects and benefits of the proposed interventions by cost-effectiveness analysis
10. Implement the selected interventions and monitor impacts.

Two quantitative estimation methods involved in the process are important to note. In the second of the 10-step process, potential mobility is to be estimated by the potential mobility index (PMI), also termed as average aerial speed. Expressed conventionally, the PMI measure suggested by Martens (2017, p. 154–155) is given by

$$PMI_i = \frac{1}{N} \sum_{j=1}^n \frac{D_{ij}}{T_{ij}}$$

where PMI_i is the potential mobility index for zone i , N is the total number of zones, D_{ij} is the aerial distance between zone i and j ,

and T_{ij} is the travel time by transportation network between zone i and zone j . Obviously, if the numerator of the measure were network distance instead of aerial distance, PMI would be a measure of level of service used in conventional transportation planning and engineering and PMI would represent average network *speed* to destinations. However, using aerial distance instead of network distance has been recommended because aerial distance represents the maximum distance. Once PMI is estimated, according to the recommended method, multiple accessibility estimates are to be obtained based on the PMI estimates considering activities such as employment, shops and stores, healthcare establishments, etc.

The other measurement of note in the TJ approach is the Accessibility Fairness Index (AFI), which is meant to denote the severity of accessibility deficiency for a region. AFI has been defined by Martens (2017, p. 160) as follows,

$$AFI_r = \frac{1}{N} \sum_{j=1}^q n_i \left[\frac{z - y_i}{z} \right]^2$$

where r stands for region r , N is the total population in region r , z is the accessibility sufficiency threshold, q is the number of groups in region r experiencing accessibility levels below sufficiency threshold z , n_i is the population size of the i -th population group below the sufficiency threshold z , and y_i is the amount of accessibility shortfall experienced by population group i . A higher AFI score for a region means greater accessibility deficiency. The equation suggests, all else being equal, the larger the regional population size (N), the smaller will be the AFI (i.e., accessibility deficiency); the larger the size of each population group below the sufficiency threshold (n), the greater will be the AFI; the larger the amount of accessibility experienced by people below the accessibility threshold (y_i), the higher will be the AFI; the higher the accessibility threshold (z), the greater will be the AFI. Martens (2017) estimates AFI for the City Region of Amsterdam, consisting of 16 municipalities, by focusing on employment access and two travel modes: car and public transit.

Although not a quantitative measure similar to PMI and AFI, another methodological contribution from the TJ proponents could be of interest to transportation planners interested in the domain of justice. That method, presented in Martens et al. (2012), recommends considering accessibility gaps between those with the highest accessibility and those with the lowest accessibility in making transportation investment decisions. In this case, the TJ proponents deviate from the typical Rawlsian maximin principle and suggests that transportation investments should seek to minimize the gap between the highest and lowest accessibility levels instead of merely maximizing accessibility for those with the lowest accessibility.

On the whole, TJ has sought to add a justice-theoretic dimension to transportation that is missing in EJ or in transportation research prior to EJ. Unlike EJ, which evolved to address existing injustices, TJ uses a theoretical framework in an attempt to establish a long-lasting equilibrium that would be considered fair by all people. For that, the TJ proponents have relied heavily on Rawlsian liberal philosophy.

Despite both EJ and TJ seeking justice in transportation, there are several notable differences between the two. First, EJ evolved in the domain of grassroots advocacy, whereas TJ evolved in academia. EJ has evolved sufficiently to demand and obtain a regulatory framework in at least one country, the US, but TJ does not have such a framework in the US or any other country. Third, both benefits and burdens are important considerations for EJ, but only benefits, especially potential mobility and accessibility, are important for TJ. Fourth, TJ excludes sustainability issues such as air pollution from transportation and focuses entirely on transportation benefits. In contrast, EJ emerged primarily to address pollution and it today it addresses both benefits and burdens of transportation. Fifth, racial and ethnic considerations are highly important for EJ, but such considerations are beyond the scope of TJ. Sixth, while non-discrimination is the primary mechanism by which justice is sought in EJ, it has no role in TJ. Finally, TJ seeks to establish a stable justice equilibrium that would be acceptable to all, but EJ makes not such effort and instead focuses on transportation agencies being compliant to rules and regulations.

Mobility Justice (MJ)

Although both TJ and MJ emerged in the same timeframe to address issues in transportation justice, they are vastly different concepts when looked at through the lens of a transportation planner or researcher. If TJ encompasses only a minute sphere of transportation, MJ covers all of transportation, and beyond. Many other authors have contributed to the emerging body of literature on MJ, but sociologist Sheller's (2018a) "*Mobility Justice: The Politics of Movement in an Age of Extremes*" is undoubtedly one of the most influential pieces on the subject. Despite MJ's growing popularity in recent years, Sheller herself notes that the concept began to take shape with Sheller and Urry (2006). Sheller's other works, such as Sheller (2018b) and Sheller (2018c), as well the works of other authors (e.g., Everuss, 2019; Cook and Butz, 2019) provide additional insights. Considering the much wider scope of MJ, the discussion below is restricted to issues related to transportation only.

In contrast to typical transportation planning, where "mobility" is defined as the ability to travel or actual travel, in MJ studies it means all movements, including migration, as well as immobility. Proponents claim that MJ can help to build political alliances to effectively address both short- and long-term problems of mobility and immobility. They justify the need for the MJ paradigm as a means to address three contemporary crises faced by the world: (1) the climate crisis, (2) the urbanization crisis, and (3) the refugee crisis. Among the three, the last, obviously, has the least to do with the current practice of transportation planning because planners mostly focus on intra-urban or intra-metropolitan transportation of people and goods. "Mobility justice is not just about transportation within cities, though that is an important part of it, but also about smaller micro-mobilities at the bodily scale that are

inflected by racial and classed processes, gendered practices, and social shaping of disabilities and sexualities” (Sheller, 2018a, p. 2). The proponents argue that both mobility and immobility are important to MJ. They recognize that mobility is not always a desired outcome because sometimes people have to travel or migrate because of coercion or housing affordability issues. Rights are important to MJ and it stands for rights to mobility as much as it stands for rights to immobility.

MJ is based on insights from EJ, TJ, and social justice. Like TJ, MJ supports the establishment of a minimum threshold of accessibility through a deliberative process, but at the same time, it is also critical of TJ for its narrow focus on accessibility. Distributive justice—the central focus of TJ—is only one of a variety of justice considerations for MJ, for it also includes deliberative justice, procedural justice, epistemic justice, and restorative justice. Deliberative justice demands not only the right to deliberate, but also the recognition of the vulnerabilities of population groups. Procedural justice demands information and meaningful participation of all populations in the process of governance. Epistemic justice demands proactive knowledge production and the bridging of knowledge gaps. Finally, restorative justice demands reparations to those harmed by transportation and environmental pollution. Thus, MJ demands not only distributive justice in transportation, but also a meaningful and informative participatory process that results in actual distribution of compensation to those harmed by transportation projects and investments.

Despite their differences, TJ and MJ also have certain similarities. First, both TJ and MJ originated from a disenchantment with status quo transportation planning practices, especially its excessive emphasis on automobile travel. Second, both view roadway congestion as a serious problem caused by the automobile culture. Third, both disdain cost-benefit analysis as a technique for measuring transportation benefits. Fourth, both emphasize the importance of space. Finally, both seek to improve the welfare of the less privileged despite having different ideas about who the less privileged are.

However, the differences between TJ and MJ are starker than their similarities. First, TJ does not consider any specific population group other than those with high accessibility and low accessibility, whereas MJ makes reference to specific population groups in terms of demographic, economic, social, and cultural characteristics. Second, TJ does not seriously consider any doctrine of justice other than Rawlsian justice (e.g., utilitarianism, libertarianism, egalitarianism, etc.), whereas MJ provides an assessment of each doctrine. Third, TJ recommends quantitative methods for application in transportation planning, but MJ does not make such efforts. Fourth, TJ is barely concerned about the role of any stakeholders in the transportation planning process, whereas MJ emphasizes the important role of community organizations and recognizes the role of government. Fifth, TJ seeks a stable reflective equilibrium in the Rawlsian way, whereas MJ seeks both short-term and long-term solutions in a dynamic world. Finally, and perhaps most importantly, TJ avoids any discussion of the distribution of the adverse effects of transportation, whereas MJ places a far greater emphasis on the correction of the adverse effects of transportation than the distribution of transportation benefits.

Conclusion

This article summarized the concepts of EJ, TJ, and MJ as related to transportation planning. It demonstrated that there are many differences between the three concepts despite having some similarities. As of now, EJ has a regulatory framework in the US, whereas TJ and MJ are merely two conceptual approaches to address transportation problems of disadvantage populations. Although TJ and MJ may appear esoteric to transportation professionals who contribute to actual plans using technical professional skills, they should investigate how these new concepts can benefit the planning process and outcomes. Transportation researchers who have the understanding of both research and practice can play a meaningful role in the integration of TJ and MJ into transportation planning.

The transportation world is a dynamic one. While most of the concerns in current EJ, TJ, and MJ literature pertain to conventional cars and public transportation, the last decade has seen substantial improvements in newer vehicle technologies (e.g., automated vehicles and electric vehicles), app-based transportation (i.e., ridesourcing), and transit service delivery models (e.g., microtransit, subsidized ridesourcing, scheduling technology, etc.). At the present time, there is significant excitement among transportation researchers about the “Three Revolutions” in transportation, consisting of electric vehicles, automated vehicles, and ridesourcing (Sperling, 2018). There is speculation among researchers that the integration of these new technologies will enable the general population to forego car ownership and use as shared mobility services provided by private companies in automated vehicles will become ubiquitous and conventional public transit will remain available only in the densest urban corridors. The justice implications of such changes cannot be known at the present time. However, given the history of injustices related to the conventional automobile, there is reason to be vigilant about potential disparate (positive and negative) impacts of new automobile technologies and service delivery models on different populations. Transportation researchers and planners concerned about justice cannot afford to lose sight on the new developments in transport technologies because they have the potential to affect not only the future of cities and transportation, but also the livelihood of future generations.

Biography

Devajyoti Deka MA (Economics), MRP, MUP, PhD (Planning), is the assistant director for research at the Alan M. Voorhees Transportation Center of Rutgers, The State University of New Jersey, New Brunswick. His research at the center predominantly addresses the transportation disadvantaged, including people with disabilities, older adults, low-income and minority populations, and children. Between 2003 and 2008, he worked as the manager for systems planning and modeling at the North Jersey

Transportation Planning Authority, where he supervised the agency's environmental justice program and managed projects pertaining to regional capital investment strategy and transportation strategy evaluation.

Introduction

The 20th century brought about a profound transformation of the way humans travel. After centuries of animal-powered locomotion, the invention of the electric and combustion engines has fundamentally changed the way humans perceived distance and conceived commercial and labor relationships. A by-product of this transformation was the change in the way human settlements and activities sound. As a matter of fact, it can be argued that, in terms of acoustic landscape (also referred to as soundscape), the 20th century is characterized by the sound of the road, railway, maritime, and airborne motorized transportation (Schafer, 1997). A harmful subproduct of this transformation is that excessive noise originating from transport vehicles has become a pervasive health hazard, especially in urban settings.

Transportation noise has been listed as a major environmental risk factor in Europe, only supplanted by air pollution (Hänninen et al., 2014). The World Health Organization (WHO) acknowledges environmental noise (dominated by transportation) as an important public health problem (WHO, 2018) and estimates that in Europe it accounts for a disability-adjusted life-year (DALY) loss of 61,000 years for ischemic heart disease (IHD), 45,000 years for cognitive impairment in children, 903,000 years for sleep disturbance, 22,000 years for tinnitus and 654,000 years for annoyance (WHO Regional Office for Europe & JRC, 2011). Therefore, despite all the benefits that came along with increasing mobility, one cannot ignore the significant burden on the health of those who are more exposed to the sound of it.

This chapter explores state-of-the-art research on the health impacts of transportation noise. It begins by defining the relevant concepts and main determinants of the transportation noise problem, following with a presentation of short- and long-term effects of noise on health. General effects of transportation noise on public health are also addressed, concluding with indications of future research.

Relevant Concepts

To facilitate the comprehension of the following sections, a set of crucial concepts related to the transportation noise problem are defined next.

Emission and Noise Sources

According to ISO 3740:2019 (ISO, 2019), emission is defined as airborne sound radiated by a well-defined noise source (e.g., the machine under test) under specified operating and mounting conditions. The basic noise emission quantities are the sound power level of the source itself and the emission sound pressure levels at the vicinity of the source. Road, rail, and aircraft transportation account for most of the transportation noise and have been the focus of most studies on specific noise sources (Lercher, 2011). The range of noise levels generated by these sources is wide. It depends on the internal components of the vehicle—such as the engine, intake system, exhaust system, fans, and structural vibration—and the vehicle–medium interaction—namely, tire–road and wheel–rail contact, water movement, and air turbulence. For road and railway traffic, rolling noise is usually the dominating noise source under typical operational conditions. While for the first the sound is generated mainly by tires–pavement interaction, for the second, it is the combined roughness of wheel and rail. Noise from aircraft is primarily caused by the engines. During landing, where engines are often in idle, airframe noise can also become relevant (Sørensen et al., 2020).

Continuous, Intermittent, and Impulsive Noise

Transportation noise can be characterized by its duration and by the way its level fluctuates. A *continuous* or *steady* noise suffers negligibly small fluctuations of level (<5 dB) within a period of observation—for example, the sound of slow-moving traffic in a busy city center; an *intermittent* noise persists for more than 1 s and then abruptly drops to the level of the background noise, showing this pattern several times during the period of observation—for example, the sound of a train passing over the rail joints and squats; an *impulsive* noise consists in a series of bursts of sound energy, each having a duration of less than 1 s and representing a change of sound pressure level of 40 dB or more within 0.5 s (Rosati and Jamesdaniel, 2020)—for example, a road vehicle rolling over rumble strips.

Noise Annoyance

The most widespread and well documented subjective response to noise is “annoyance,” which is a multidimensional negative reaction that covers: (1) immediate behavioral noise effects aspects, such as “disturbance” and “interference in ongoing activities,” and (2) evaluative aspects such as “nuisance,” “unpleasantness,” and “getting on one’s nerves” (Guski et al., 1999). It may also include feelings of fear and mild anger related to a belief that one is being avoidably harmed (Stansfeld and Matheson, 2003).

Noise Exposure–Response Relation (ERR) Curves

It is the strength of association between exposure to environmental noise and long-term noise annoyance, as demonstrated by the percentage of highly annoyed residents (%HA) as a function of noise level (usually expressed in L_{den} , as discussed in a recent meta-analysis by (Guski et al., 2017)). The exposure–response relation can be different for different noise sources and combinations of noise sources. The current literature shows steeper increments in ERR curves for exposure to air transportation, followed by exposure to railway transportation, and with the lower rate of increment in %HA being found in exposure to road traffic (Guski et al., 2017).

Environmental Noise Management

Also designated by *environmental noise control*, according to Brown and Van Kamp (2015) includes technical interventions that embrace reduction of levels at the source (e.g., low noise road pavements and vehicle engines), positioning of outdoor barriers between source and receivers, and changes in the acoustic properties of building envelopes to reduce levels at receivers.

Response Mechanism to Noise Exposure

Noise exposure may be associated with stress responses, characterized by activation of the neuroendocrine system (i.e., hypothalamus–pituitary–adrenal (HPA) axis and sympathetic–adrenal–medulla axis), and a subsequent release of stress hormones (Cantuaria et al., 2018). For example, associations between exposure to transportation noise and stress-induced secretion of glucocorticoids, mostly cortisol in children and adults, were empirically demonstrated. In newborn infants, it is suspected that road traffic noise exposure may act as a potential environmental stressor in early postnatal life, which might have a possible physiological relevance later in life (Cantuaria et al., 2018).

There is a multitude of possible effects of transportation noise on health. They have mainly been grouped by the duration of symptomatology as short and long-term effects (Porter et al., 2000). Short-term effects are the result of annoyance expressed during one or few hours, while long-term effects or chronic annoyance designates a feeling that has been felt over months and years (Bartels et al., 2015). In the next sections, the distinction between short and long-term effects of traffic noise will be clarified by describing the most common health consequences of each.

Short-Term Effects of Noise on Health

Short-Term Annoyance

The annoyance response is seen by many researchers as a stress-reaction involving an environmental threat and individual physiological, emotional, cognitive, and behavioral responses, which can partly be remembered and integrated into a verbal long-term annoyance response (Guski et al., 2017).

Figure 1 Examples of noise-response curves from the European Environment Agency (EEA) (Babisch et al., 2010), the Sirene project (Brink et al., 2019), and WHO (World Health Organization, 2018).

Different time dimensions of annoyance can be distinguished. Short-term annoyance refers to a response regarding noise exposure during a limited period, for instance, the previous night. Long-term annoyance describes a general feeling that has evolved over longer periods, of weeks, months, or even years. Long-term annoyance is considered to result from the accumulation of acute physiological responses to a noise event, and short-term to reactions in the day after a disturbed night's sleep, that is, acute responses resulting from awakenings in the previous night and possibly perceived fatigue and cognitive performance decrements. According to Porter et al. (2000), all levels of annoyance have the same causes and share the same characteristics despite their different orders of time. Also, there is some evidence that short-term annoyance is related to long-term annoyance.

The prediction of annoyance has been based on exposure-response curves. In general, for each traffic noise, these curves describe an increase in annoyance with rising exposure (Fig. 1). The European Environment Agency recommends those provided by the EU-position paper on dose-effect relations (Babisch et al., 2010) to predict the annoyance from road traffic, aircraft, and railways (separately for each noise source). Also, the WHO recommended in the 2018 guidelines (World Health Organization, 2018) the curves proposed in Guski et al. (2017). Recent studies indicate that people react more strongly to a given noise exposure level today than in the past, as it was shown in the Sirene project (Brink et al., 2019; Foraster et al., 2019).

Average noise levels are often selected as an acoustical measure to predict noise annoyance, but noise affected persons do not only react to a global noise exposure, characterized by the average noise level, but also to the characteristics of noise events, that is, to number, distribution, duration, level, and meaning of noise exposure. For example, Quehl et al. (2017) showed the importance of the number of overflights for the prediction of short-term annoyance due to nocturnal aircraft noise. Other approaches based on psychoacoustical indexes have also been explored to explain short-term annoyance. They have been used, for example, to characterize annoying auditory sensations evoked by railway pass-by noises in urban areas (Catherine et al., 2018) or to develop short-term annoyance models as Chun et al. (2018) did for combined aircraft and road traffic noises.

Sleep Disturbance

Sleep disturbance refers to internal/external interference with sleep onset or sleep continuity (Basner and McGuire, 2018). Undisturbed sleep is a prerequisite for high daytime performance, wellbeing, and health. Noise is a common cause of sleep disturbance because the sleeping brain retains its ability to process incoming acoustic stimuli (Jafari et al., 2018). The auditory system has a watchman function and constantly scans the environment for potential threats. Humans perceive, evaluate, and react to environmental sounds even while asleep. These reactions are part of an integral activation process of the organism that expresses itself, for example, as changes in sleep structure (sleep structure varies systematically over the course of the night, with deep sleep stage N3 (stage 3 or 4 according to the old classification) dominating the first half of the night and REM sleep and superficial sleep stages N1 and N2 (1 and 2) dominating the second half of the night) or increases in blood pressure and heart rate (Schmidt et al., 2013).

Noise has been shown to fragment sleep, reduce sleep continuity, and reduce total sleep time. The noise effects on sleep are well illustrated in Fig. 2. At short-term, noise-induced sleep disturbance include impaired mood, subjectively and objectively increased daytime sleepiness, and impaired cognitive performance (Basner and McGuire, 2018). Over long time-periods, health consequences such as cardiovascular and metabolic diseases may develop. Too much noise at night may also lead to chronic partial sleep loss, which plays a role in the current epidemics of obesity and diabetes (Sørensen et al., 2020).

There is evidence that physiological, unconscious reactions during sleep are different from psychological, conscious reactions during wakefulness, and cannot be predicted from annoyance surveys (Elmenhorst et al., 2019). During the night, transportation noise can often be described as intermittent (i.e., discrete noise events rather than a constant background noise level). When the organism differentiates a noise event from the background, physiologic reactions during sleep can be expected (Basner and McGuire, 2018).

Among those reactions is the awakening, which refers to events where a subject wakes up from sleep, regains consciousness, and recalls it in the next morning. There is evidence that the different modes of transportation affect awakenings in several manners. The

Figure 2 Effects of noise on sleep (Adapted from Basner and McGuire, 2018).

several traffic noise sources induce different awakening probabilities even at equal maximum A-weighted sound pressure level (SPL) and similar acoustical parameters, like rise time of the maximum A-weighted SPL of a noise event, number, and duration of noise events, as well as physiological parameters like current sleep stage, elapsed sleep time, and elapsed sleep time in the same sleep stage. At equal maximum A-weighted SPL the awakening probability due to the three traffic noise sources increased in the order aircraft < road < railway noise (Elmenhorst et al., 2019). This rank order of traffic modes was obtained in laboratory studies. Thus, it is different from expose-response curves obtained from self-reported studies. These studies are based on responses to questions, for example, the ones related to awakenings analyzed in (Basner and McGuire, 2018; Brink et al., 2019) or annoyance as discussed in (Lechner et al., 2019), where aircraft noise causes higher reactions, followed by railway, and then road traffic noise.

The number and acoustical properties of single noise events reflect better the actual degree of nocturnal sleep disturbance in a single night than equivalent noise levels (Basner and McGuire, 2018). As reported by Elmenhorst et al. (2019), the spectral characteristics of noise from the different traffic noise sources might explain the differences between reactions. Especially high frequencies that are filtered for aircraft noise via the atmosphere were found to explain differences in awakening probability between traffic noise sources. For railway noise, high-frequency components are more likely to induce event-related arousals and increases in heart rate than low-frequency events (Smith et al., 2019). Also, the fluctuations in freight train sounds, as well as its sharpness, were found to have an impact.

Cortical Awakenings caused by road, rail, and aircraft noise measured by polysomnography (simultaneous measurement of at least brain electrical potentials, eye movements, and muscle tone) showed a positive association between indoor maximum noise levels of single events and the probability of sleep stage transitions to wake or Stage 1 for all transportation modes (Basner and McGuire, 2018). Also, the noise levels at which the probability of an additional awakening may occur differs between transportation modes, and are between 33 and 38 dBA (Basner and McGuire, 2018).

A recent study confirmed effects from the nighttime transportation noise events on increased sleep electroencephalography arousal indices. In this study, sleep structure and continuity were not affected (Rudzik et al., 2020). Nevertheless, it was found that the amplitude of sleep spindles (which have a sleep-protective function and are relevant for memory consolidation) was consistently decreased during noise exposure compared with noise-free nights (Münzel et al., 2020).

Noise at the beginning of the night impairs the process of falling asleep but may be compensated later. In contrast, even short periods of noise toward the end of the sleeping period cause sleep disturbances. This finding is supported both by laboratory studies and observational studies on self-reported sleep quality in the morning (Münzel et al., 2020).

Long-Term Effects of Noise on Health

While short-term effects of transportation noise have been deeply studied and are well documented, there is a growing body of research concerning the effects of long-term exposure on physical and mental health. There is particularly strong evidence for a relation between noise and cardiovascular and metabolic disease, impairment of cognitive development (in children), and mental disease (Sørensen et al., 2020). More recent studies have also pointed to a relation between transportation noise and cancer (e.g., Hegewald et al., 2017) and metabolic diseases (e.g., Foraster et al., 2018).

Cardiovascular Disease

Several researchers have been studying the relation between transportation noise and cardiac disease, in both laboratory and real-life environments. Noise (particularly through sleep disruption and stress-related reactions) increases sympathetic and endocrine responses increasing on oxidative stress (Munzel et al., 2014) and inflammatory or immune responses (Münzel et al., 2017). This may lead to increases in blood viscosity, blood coagulation, and blood pressure (Lundberg, 1999), which are known risk factors for cardiac disease. Two cardiac conditions have been extensively studied concerning transportation noise: hypertension and ischemic heart disease (IHD). Regarding hypertension, several studies explored its relation with noise (Babisch, 2014; Babisch et al., 2009; Huang et al., 2015; Jarup et al., 2008; Schmidt et al., 2015; Van Kempen et al., 2006) with mixed results. Large scale studies like the ones undertaken in projects RANCH (Van Kempen et al., 2006) and HYENA (Jarup et al., 2008) have pointed to increased risk of hypertension resulting from long-term noise exposure to aircraft and road traffic. A subsequent meta-analysis found increases in the risk of hypertension from transportation noise, particularly aircraft noise (Babisch, 2014; Babisch and Van Kamp, 2009; Huang et al., 2015). A systematic review by WHO combining 37 studies found significant positive risk estimates for prevalent hypertension, for aircraft, railway and traffic noise (van Kempen et al., 2018). However, the WHO analysis was mostly comprised of cross-sectional studies and thus the quality of the evidence was ranked “very low.” More recent cohort studies (Dimakopoulou et al., 2016; Pyko et al., 2018) have also found association between noise and increased risk of hypertension.

IHD has also been consistently connected with long-term noise exposure. Meta-analysis has shown associations with road traffic (Babisch, 2008, 2014) and aircraft traffic (Vienneau et al., 2015). The systematic review by WHO evaluated 22 articles and found several associations between transport noise (aircraft, traffic, and rail) and IHD. Particularly, evidence for a relation with traffic noise was deemed as “high” quality, due to the existence of several cohort studies supporting the association.

Transportation noise may also increase the risk of other cardiac diseases such as stroke (Halonen et al., 2015; Héritier et al., 2019; Pyko et al., 2019; Seidler et al., 2018).

Effects on Cognitive Development

Transportation noise is hypothesized to have effects on cognitive development, so several research works focus on understanding the effects of noise in children at school age. Noise may affect children’s cognitive development through factors such as annoyance, distraction, reduction speech intelligibility, increased arousal, learned helplessness, frustration, and indirect effects caused by sleep disturbance (Basner et al., 2014; Shield & Dockrell, 2003).

Multiple studies support the association between noise exposure and impairments in reading and oral comprehension, memory, attention, and Standard assessment tests (SATs) (see Clark and Paunovic, 2018a for a review). The majority of the studies concerns with children exposure to aircraft or freeway traffic while in school (Sophie et al., 2014). Of particular interest is the study of Evans et al., who analyzed the consequences of the relocation of the Munich airport on children’s health and cognition (Evans et al., 1998; Hygge et al., 2002). They found that deficits in reading comprehension and long-term memory in children exposed to noise of the old airport disappeared two years after the relocation. Conversely, similar deficits developed in children exposed to noise originating from the new airport. The large-scale RANCH study comprising children from Spain, the Netherlands and the UK living near airports also found negative effects of aircraft noise exposure on reading comprehension and recognition memory, after adjusting for a range of socio-economic factors (Clark et al., 2006; Stansfeld et al., 2005).

A WHO systematic review (Clark and Paunovic, 2018a) found a significant association between exposure to aircraft noise and oral and reading comprehension as well as SATs tests, and performance on short- and long-term (Episodic) memory. The authors rated the evidence of both associations as medium quality. Evidence concerning the effects of traffic and rail noise was generally considered less consistent, which may be due to a limited number of studies, cross-sectional designs that do not allow to infer causality relations, and inconsistent performance assessment methods.

Mental Health

Transportation noise is regarded as environmental stress cause and continuous exposure is seen as a risk factor in the development of latent mental health issues (Berglund et al., 1999). A possible pathway for such effect is the increase of autonomic response and production of stress hormones, which may lead to the development of depression and anxiety disorders (Berglund et al., 1999).

Nevertheless, evidence for specific connections between noise and mental wealth is still scarce. A systematic review by WHO has pointed to a connection between exposure to road and railway noise and emotional conduct disorders, and road noise and hyperactivity in children (Clark and Paunovic, 2018b). The same report also evaluated evidence for connections between noise and measures of depression and anxiety, but they were generally considered low quality, since there are few studies, they are mostly cross-sectional, have small samples and vary substantially in methodological terms (Sørensen et al., 2020). Similar conclusions were drawn by (Sakhvidi et al., 2018) in another systematic review focused on children. As for adults, there is some recent evidence supporting a relation between noise and depression (Eze et al., 2020; Seidler et al., 2017). The cohort study by (Eze et al., 2020) shows that this relation may be mediated by annoyance, as exposure per se was only loosely related with depression. This is further supported by findings of the Gutenberg Health Study (Beutel et al., 2020) a longitudinal study with a large community sample exposed to multiple noise sources including aircraft, road, and railways. The study concluded that daytime baseline aircraft annoyance is a predictor of depression and anxiety.

Other Long-Term Effects

Cancer

A relation between transportation noise and cancer is hypothesized (Sørensen et al., 2020), possibly through long-term sleep disruption and induced stress, which are known to affect hormonal processes (Babisch et al., 2001). There is some evidence of a connection between transport noise and breast cancer (Hegewald et al., 2017; Sørensen et al., 2014), and colon cancer (Roswall et al., 2017), although research is still scarce.

Diabetes

There is some evidence of a correlation between long-term exposure to noise and the onset of diabetes. A recent meta-analysis by (Sakhvidi et al., 2018) has reviewed 15 studies on the relation between noise exposure (including several related with transportation noise) and diabetes mellitus. They found a 6% increase in the risk of diabetes mellitus for a 5 dB increase in noise exposure, mainly related to air and road traffic.

Obesity

There is evidence of a connection between noise exposure and obesity markers, such as body mass index (BMI) and waist circumference (Foraster et al., 2018; Pyko et al., 2015, 2017).

Pregnancy

There is some research relating transportation noise exposure with birth outcomes such as reduced weight, size of the newborn, and preterm birth (e.g., Smith et al., 2017; Wallas et al., 2019). A recent meta-analysis by (Dzhambov and Lercher, 2019) found only moderate-quality evidence for a relation between noise and lower birth weight, although they have identified trends related with other variables such as the reduced size for gestational age, highlighting the need for further studies.

Future Research

Exposure to transportation noise is today an important public health issue, especially for the urban population. While the issue has been the subject of intense research, there is still a considerable amount of unknowns, especially regarding the consequences of long-term exposure. Many of the studies conducted so far were done with small samples and/or relied on cross-sectional designs, making difficult the deduction of causality relations. Such seems to be one of the main conclusions of several systematic reviews commissioned by the WHO (Clark and Paunovic, 2018a, 2018b; van Kempen et al., 2018) as well as others conducted independently (Sakhvidi et al., 2018). Benefits could also be drawn from more unified approaches in the measurement and categorization of noise sources and the corresponding health outcomes, that would facilitate comparisons and meta-analysis.

Attention must also be paid to the role of confounders. Many recent studies now account for the role of air pollution exposure, which often comes hand to hand with noise exposure (Stansfeld et al., 2015; Vienneau et al., 2015). However, other factors need to be addressed, such as socio-economic factors, life-factors, gender, and pre-existing physical and mental conditions (Belojevic and Evans, 2012; van Kempen et al., 2012). Age-specific factors should also be accounted for. While children and elders are often pointed as more vulnerable populations, there is some evidence that they are less sensitive to noise annoyance than middle-age people (Van Gerven et al., 2009), which may indicate less risk of health effects. Possible explanations may be either a relation with maturation and decline of neurocognitive functions, respectively in children and elderly, or a higher average mental workload in middle age, which limits the ability to cope with noise (Van Gerven et al., 2009). Nevertheless, apart from annoyance, children may be prone to hindrances in cognitive development (see section "Effects on cognitive development"), while elders are generally more vulnerable to cardiovascular and metabolic diseases. The specificity of these age groups should therefore be studied.

Understanding the pathways through which noise affects physical and mental condition is also an important research goal. Chronic stress and sleep disturbance are often pointed as pathways to consequences in physical and mental health. The study by Eze et al. (2020) pointed to an annoyance pathway between noise and depression. Additional research is needed for understanding the hazard mechanisms and establish relations between short and long-term effects.

As transportation noise has severe consequences on health, the WHO proposed maximum limits to noise exposure. A provocative question can be asked of whether minimum limits should not also be proposed. New energy vehicles are generally less noisy than their combustion counterparts at lower speeds (like the ones practiced in urban centers). A reduction in urban noise is expected in the next years, even if only a modest adoption of these vehicles occurs (Campello-Vicente et al., 2017). However, if the change can bring positive health outcomes, there is the risk of an increase in the number of traffic crashes involving pedestrians. The vehicle industry has been trying to solve the issue by introducing artificial noises at low speeds. However, this solution can offset the benefits of a reduction in engine noise and may increase traffic noise annoyance. Understanding how low noise emission affects the vehicles' detection and localization by pedestrians, particularly by blind or visually impaired ones, is thus an important research goal if we intend to take full advantage of the noise reduction potential of electric motorization. So far, studies addressing the influence of vehicular noise on pedestrian crossing decision-making are rare, and their scope is limited. It seems that noise may not be the most important cue to ensure safe road crossing decisions by unimpaired adults (Pugliese et al., 2020; Soares et al., 2020), at least when the car is in sight. However, the same may not apply regarding the detection of nonvisible vehicles (Barton et al., 2012). In conclusion, more insight into the tradeoff between traffic noise and safety is relevant to mitigate noise effects on public health.

The new mobility paradigms allied to the alternative energy sources, with the consequent changes in noise patterns and characteristics of the vehicles, reinforce the need to keep studying and innovating on the approach to short-term effects of traffic noise on public health. Some researchers are already looking for acoustic and psychoacoustic alternative noise indicators to explain reactions to traffic noise.

Noise mitigation measures at the engineering level have been proposed to reduce the noise arriving at dwellings by acting on the source, propagation paths, and buildings (receptors). However, acting on the source is beneficial in many aspects as we all appreciate to walk on the street or open the window at home or work and find a pleasant, nonannoying soundscape. Carrying out more interdisciplinary research involving vehicles' and components' manufacturers, transportation and health professionals, and policy-makers will drive to cost-effective solutions to change to healthy and safe traffic noise levels and characteristics.

The Strong Links Between Transport and Climate Change

The reality of anthropogenic climate change is not just one of incremental deviation from typical temperature and climate conditions, with warmer summers for some, shorter winters for others and more common extreme weather events. Climate change means increasing likelihood of abrupt, unpredictable and drastic global changes that will suddenly disrupt our and other species' lives, livelihoods and wellbeing (Lenton et al., 2008). The magnitude of these damages is expected to be far greater what we have experienced during the recent COVID-19 pandemic, for the price in human lives, geographical extent, involvement of different life forms and irreversibility. It is not a surprise then that the rapidly changing climate is becoming a key concern for citizens across the world, and that transport policy and planning have been increasingly called into question for not adequately addressing what ought to be a key objective.

Evidence shows that reducing transport-related carbon emissions is a vital step toward the avoidance of catastrophic climate change and that, at the same time, transport is one of the most challenging sectors to decarbonise (IPCC, 2018). Despite multiple sustainable transport initiatives, emissions from the sector have stubbornly continued to grow. In 2017, transport worldwide accounted for 25% of carbon emissions and, between 2010 and 2017, for half of their global growth (IEA, 2018). Although the COVID-19 pandemic brought a temporary and unexpectedly substantial decrease in emissions, maintaining these positive effects, and effectively and permanently decarbonising the sector, ought to be a national and international priority. At the same time, there is evidence that this still constitutes a substantial challenge, as it requires a radical reconfiguration of lifestyles and cities, with a major reduction in car dependency, long-distance travel, carbon-intensive import-export markets, etc. (Schwanen, 2019).

In this chapter I will explore the way in which climate change is strongly linked to current high-carbon transport systems and human health in a negative, self-reinforcing cycle, the risks we face if no action is taken and the possibilities we still have to break this negative cycle.

High-Carbon Transport Systems

"High-carbon transport system" (HCTS) is a term that can help us describe the key features of most established transport systems^a in Western society, which are becoming increasingly popular in other global regions. HCTS include what the academic literature has described as the systems of "automobility" and "aeromobility," expanding paradigms of mobility practices, technological and infrastructural developments, land use patterns, and modes of production and consumption that lock-in car (and increasingly air-travel) dependency (Freund, 2014; Lassen, 2016; Paterson, 2007). This dominance of the private car and, more recently, long-distance hypermobility via flying, are the cardinal points of worldwide transport systems and, more broadly, oil-based economies (Mattioli et al., 2020). Automobility and aeromobility are planned on the assumption that favoring speed, efficiency, and economic growth equates with increasing social benefits (Schwanen, 2019). They constitute a salient feature of neoliberal urban development and are, evidently, a major contributor to global CO₂ emissions and air pollution (Freund, 2014; Paterson, 2007). They have key and widespread negative impacts on health and wellbeing across several geographies (Khreis et al., 2016). As depicted in the diagram below, HCTS directly generate health impacts and directly contribute to climate change, which, in turn, indirectly increases the negative health effects, as I will show in the next sections of this chapter (Figure 1).

^a With transport systems here I refer to what Schwanen (2019, np) calls "transport configurations – the ensembles of infrastructures, technologies, practices, regulation, meanings, values, affects enabling and shaping the (non)movements through physical space of people, goods and waste".

Figure 1 The relation between HCTS, health and climate change

The Links Between Climate-Change and High-Carbon Transport Systems

Interdisciplinary research efforts have now confirmed that the current drastic changes in climate are not just fluctuations of temperature as traditionally experienced in our planet's history, but substantial deviation from average temperature as a result of disproportionate release of carbon dioxide (CO₂) and other greenhouse gasses (such as black carbon and methane) in the atmosphere. CO₂ concentration are reaching a value higher than at any time in at least 800,000 years, a 40% increase with respect to historic trends (IPCC, 2018). These gasses are released as a result of most human activities involving combustion of fossil fuel and changes in land-use, including farming and deforestation (IPCC, 2019). To date, these carbon-intensive human activities have caused between 0.8 and 1.2 of global warming with the expectation of an increase to 1.5 by 2052, if there is no change (IPCC, 2018). The damaging effects of this anthropogenic global warming are becoming increasingly evident and are predicted to get much more severe. They include sea level rises, heat waves, heavy rainfalls and floods, forests dieback, biodiversity losses, increase risk of vector-borne diseases, etc. (Lenton et al., 2008).

The transport sector is the second largest and still growing contributor to global greenhouse gas emissions and especially CO₂, the backbone of climate change, therefore the name HCTS. Despite improvements in other sectors, at the beginning of 2020, transportation was still responsible for 24% of direct CO₂ emissions from fuel combustion, an immense responsibility in an era of climate crisis (FAOSTAT, 2020; IEA, 2020). This is the result of automobility and aeromobility being fundamentally oil-based: the high number of road vehicles used in Western countries and, increasingly, globally (GHO, 2020) accounts for almost three-quarters of the emissions from the transport sectors. Improvements related to electric vehicle adoption are rapidly outpaced by the higher emissions of increasingly popular SUVs, whilst aviation and shipping emissions continue to rise faster than any other sector (Chapman, 2007; IEA, 2020).

We can therefore clearly state that transport, as HCTS, is a key cause of anthropogenic climate change. This has been widely acknowledged, with climate change mitigation becoming a key topic in transport studies and increasingly transport policy (see for example (DfT, 2020). Although the magnitude of the work published in this direction is too large to be reviewed in this chapter [for a summary of works on climate change in transport geography see for example Schwanen (2019)] some key themes are emerging when considering mitigation pathways, as I will explore in the last section of this chapter.

At the same time, extreme weather events related to climate change have important impacts on transport systems, operations, and their resilience (Budnitz et al., 2020), and in recent years there has been an expansion in research considering potential climate change adaptation paths in the field, for example focusing on sea level rise impact on coastal transport infrastructure (Dawson et al., 2016), or changing travel behaviors as consequence of higher temperatures (Ferranti et al., 2017).

The Health Implications of High-Carbon Transport Systems

HCTS have notoriously negative impacts on human health and wellbeing. These can be grouped in three main areas: direct impact on individual health, secondary impacts on generalized health as result of changes in behaviors and the environment, and broader societal impacts.

First, as reported by the WHO (2020), approximately 1.35 million people die each year worldwide as a result of road traffic crashes. Road traffic is the leading cause of death for people aged 5–29 years, effectively generating an immense and silent genocide that has been globally accepted in a “rather unquestioning manner” (Wells and Beynon, 2011, p.2494). Although this effect is not necessarily linked to the type of combustion engine utilized, transport systems designed around the private car, with their high consumption of public space and high speeds, are substantially intertwined with an uneven system of “death and violence,” in which the ones that are most affected are non-car users. This effect is sharpened in poorer countries where traffic accident victims are often young adults from less wealthy groups (Culver, 2018; Wells and Beynon, 2011). As suggested by Culver (2018), fundamental justice issues permeate the way pedestrians and cyclists suffer the most from someone else's use of a motor vehicle. This injustice, as will be

evident in the next sections, applies not only to the distribution of damage related to traffic accidents, but also to the health impacts related to traffic emissions.

Second, the high number of road vehicles generate substantial changes to the environment which impact human health. HCTS do not only contribute to greenhouse gas emissions, but are also a key source of air pollution, being responsible for a high proportion of particulate matter circulating in the atmosphere as well as other pollutants such as NO, NO₂, carbon-monoxide, and other volatile organic compounds such as benzene and ethene. These are released both via exhaust emissions and as consequence of wear and tear phenomena (e.g., tyres and brakes), and are proven to generate vast negative health effects such as cardiovascular, cerebral-vascular and respiratory mortality and morbidity, decreased lung function in children, and diabetes (Landrigan et al., 2018; Khreis et al., 2016). Similar negative effects are also linked to the high level of traffic-related noise. Furthermore, as widely acknowledged, a vast burden of disease is linked to the sedentary life-style that car-dependency promotes. Lack of physical activity is linked to cardiovascular diseases, cerebrovascular disease, cancer (colon, breast, and lung), type 2 diabetes, dementia, anxiety, depression, obesity (Khreis et al., 2016). To these need to be added the unexpectedly substantial negative health impacts associated with the reduced availability of green space and biodiversity loss as a consequence of car-centred planning that, together with a culture of speed and efficiency linked to car-centered societies, has substantial damaging mental health and inflammatory outcomes (Nieuwenhuijsen, 2020).

Finally, key societal inequalities are embedded in HCTS which indirectly result in health issues. These are of great concern and their magnitude becomes clearer if we adopt a framework in which health is linked to wider discussions around human wellbeing. Although several definitions of what wellbeing entails are possible, it can be linked to the possibility for each individual to live a fulfilling life by, for example, being able to access and perform activities which she values (Sen, 2010). In this sense, transport is directly responsible for allowing people to access and perform most of these activities and therefore reach a suitable level of wellbeing.

Following this, or other complementary ideas around wellbeing, the transport and mobilities literature is increasingly highlighting the strong inequality outcomes of HCTS (Verlinghieri and Schwanen, 2020). The uneven access that different population groups have to a car in a world designed around it (Mattioli et al., 2018)^b, coupled with the very limited availability of alternatives (both because of affordability and reach of services) generate “transport poverty” (Lucas et al., 2016). This forced immobility or the high cost^c of mobility, heavily impacts people’s ability to access healthcare, education, appropriate livelihoods, social networks, and therefore their generalized wellbeing. Similarly, poorest groups are also the most affected by transport related air pollution, even though they emit the least (Jephcote et al., 2016). These impacts are unevenly distributed also with relation to income, gender, race, age, sexual orientation, and their intersection, and are particularly felt with new established HCTS in non-western countries (Uteng and Lucas, 2018).

The Health Implications of a Changing Climate

Warmer weather and extreme weather events are reported to have substantial health impacts for all and especially most vulnerable and less mobile individuals. Climate change is likely to increase thermal-related mortality, water/food/vector-borne diseases, skin cancers, malnutrition, respiratory diseases linked to augmented air pollution, as well as direct increase in injury and deaths as effect of extreme climate events (Nichols et al., 2009). Extreme weather will also make walking, that is the predominant mean of transport for the poor in most countries, unsustainable.

At the same time, extreme climate event as well as long-term environmental changes such as droughts, will generate important mental health effects, damage livelihoods of already vulnerable population with resulting lack of access to land or clean water, forced mass migrations and broadening of societal inequalities. As UNDP reported already in 2007, “increased exposure to drought, to more intense storms, to floods and environmental stress is holding back the efforts of the world’s poor to build a better life for themselves and their children” (UNDP, 2007; p.1).

Environmental and climate justice movements have been highlighting these dangers for decades and have developed a clear agenda that addresses the uneven distribution of climate change effects and the substantial changes needed in our society and economies to address those (Routledge et al., 2018). Their analysis points out the unjust outcomes of HCTS. While wealthier citizens in the West (or, as minorities in non-western countries) benefit from the availability and comfort of automobility and aeromobility, and of the related government and private sectors investments which strongly sustain their car-centered lifestyles (Mattioli et al., 2020) and their opportunity for seamless long-distance air-travels, most vulnerable groups across different geographies pay the price of this highly unsustainable systems. These people, that often rely solely on walking and, are effected both directly in their individual health, and more broadly and profoundly in terms of irreversible damages to their livelihoods, economies, social networks and cultures.

^b Or the high price of maintaining one for some groups forced to do so to reach their livelihoods, even though maintaining a vehicle costs an unacceptably high proportion of their disposable income.

^c Here with cost I intend to include also the non-monetary aspects that are linked to unequal transport systems, in terms of safety, discomfort, risk of harassment, etc. which are mostly paid by minorities.

How We can Tackle Adverse Health Impacts and at the Same Time Reduce Climate Change by Rethinking our Transport Systems

From the analysis presented, it is clear that there is a strong link between automobility, aeromobility, and climate change and that efforts to reduce the health impacts of both have to be directed toward shifting human mobilities away from the focus on the private car and, more generally, away from high-carbon transport systems.

Academics and policy makers have suggested several different pathways to reduce carbon emissions from transport. These act at different levels of transport systems that, for simplicity and following the definition from Timms et al. (2014), can be grouped as changes in *physical infrastructures*, *mobilities*, and *planning and governance*. As I show in the remainder of this chapter, if considered as a whole, these pathways might be able to direct us toward starting to challenge automobility and tackle its damaging impacts on health and the climate.

Changes in the Physical Infrastructure of Transport Systems

This level is traditionally considered central in tackling climate change. Technological change and modernization, as well as the construction of transport infrastructures, have been and still are at the core of transport research and policy, and attract substantial public and private investment. Vehicle and fuel efficiency, electrification, and automation are seen as the key premises for both less-carbon intensive and less polluting transport futures. In the United Kingdom, for example, they are the backbone of the £1.5 billion investment as part of the DfT's recent Road to Zero strategy (DfT, 2018), which includes end of sale of traditional diesel and petrol cars, substantive incentives for EVs purchase, development and charging infrastructures, wide adoption of low-emission fuels, and development and adoption of new low-emissions technologies.

Automation and smart technologies are also believed to facilitate a transition to less-carbon intensive transport systems as, with specific implementation conditions, they could provide new avenues for changing travel patterns and behaviors, with more potential for diminishing car ownership via on-demand mobility services, as well as the adoption of energy-saving driving practices and more efficient vehicles (Wadud et al., 2016).

However, there are some substantial challenges in tackling adverse health impacts of our transport systems and at the same time reducing climate change by solely improving transport technologies.

First, coordinating efforts toward carbon and air pollution reduction and human wellbeing, is a great challenge, and some of the solutions that might lower carbon emissions may have damaging social effects (Mattioli, 2016). For example, current EVs technologies do not reduce traffic accidents. Similarly, they are still very high in PM emissions (Timmers and Achten, 2016) and there is a lack of clarity on the precise full life-cycle emissions of both new vehicles and supporting infrastructure production. Automation and AI for shared mobilities come with huge privacy and data use issues that are still far to be solved. Moreover, some infrastructural developments have key distributional impacts, either because they encourage the phenomena of gentrification or more simply through their allocation of substantial incentives and resources to facilitate the movements of groups that are already among the most mobile (Schwanen, 2020). New technologies won't be affordable for great part of population and surely for the most vulnerable groups in the poorest countries. Directing urban development toward accommodating primarily technologies that are accessible only to high income groups risks exacerbating the transport poverty of vulnerable groups who already pay greatly in terms of health and wellbeing impacts.

Finally, there is a risk that the economic benefits of higher vehicle efficiency (or perceived safety as for automated cars) may further encourage car ownership, further locking-in, with substantial development of hard infrastructures for private mobility, car dependency, and preventing the development of alternative options (Henderson, 2020). Overall, there is a clear risk that the proposed technological advancement if considered on its own or as the core of any future transport strategy, will not be able to challenge the patterns of land use and travel behaviors, as well as the logic of efficiency, acceleration and growth that is fundamental to automobility and key in the worsening of the climate emergency (Schwanen, 2019).

Changes in Mobilities

In Timms et al. (2014), the definition of transport systems uses the term "mobilities" to refer to the movements of people and goods across space. Academically, the term is also used to indicate a research direction that, in the last decade, has highlighted the crucial role of movement in shaping not only transport systems, but the entire society (Sheller and Urry, 2006, 2016). The "mobilities tradition" complements traditional transport studies by looking beyond mere physical movements "from A to B," and focusing on the *meanings* and *practices* that individuals and society associate with these movements. By asking questions such as: "Why do we make journeys from one place to another?"; "What modes of transport do different people use?"; "How exactly do they use them?"; and "How do they shape what we are and the way we live?," it highlights the different dimensions that influence travel and movements and how they are differentially experienced by people or shape their lives.

The mobilities tradition can be of help when looking at changes to transport systems traditionally framed in terms of "modal shift" or "behavioral changes." These include changes in travel in terms of: (1) which vehicle is used -promoting the adoption, for example, of walking or cycling or public transport-, (2) frequency and length of journeys, -for example promoting trip-chaining or changes in land use-, (3) a combination of the two, for example, with the idea of Mobility as a Service (MaaS). Several strategies have been adopted to implement these changes, including information campaigns, investments in public

transport or walking and cycling infrastructures and trainings, taxation measures for vehicles, new ticketing options, changes in land-use (Nieuwenhuijsen, 2020).

These strategies are promising in their ability to be effective in reducing carbon emissions and, at the same time, promoting healthy outcomes. There is widespread evidence of the health benefits of walking and cycling, with the associated physical activity outweighing the risk of road accidents or increased air pollution exposure. Similarly, land use changes that, via greater density, diversification of use and better design, promote greater accessibility to key destinations by walking, cycling or public transport, result also in widespread health benefits. Among all, the example of the Barcelona's super blocks provide evidence of how well-designed land-use changes combined with strategies to recover public and green space and therefore reduce car use have enormous health benefits (Nieuwenhuijsen, 2020).

However, convincing people to give up their cars and shift to other ways of moving has proven to be a great challenge and the widespread and lasting adoption of low-carbon mobilities still has far to go. The mobilities literature provides an explanation for this, showing how specific travel practices are far from being the result of an individual rational and weighted choice. They are part of a broad socio-technical system in which available technologies and materials, cultural norms and values, personal experiences and habits interlock with specific travel practices (Stephenson et al., 2015). Ideas of freedom, privacy, comfort, and individuality associated with the private car are reinforced and replicated in car adverts, movies, societal discourses and personal experiences, making car dependence a much stronger habit that we might initially imagine (Paterson, 2007). At the same time, the adoption of new mobility practices, especially when including a new series of bodily movements, knowledge, skills, and resources, such as cycling or utilizing MaaS, might become an unsurmountable challenge for resource-scarce groups of the population whose survival is tied to the availability of the car. The gilets jaunes movement in France or the recent mobilizations in Chile have shown how much urban livelihoods are tight to transport pricing. Similarly, the same act of walking or biking might be perceived as socially unacceptable or extremely unsafe for certain groups, especially women or minorities (Law, 1999), so that certain investments once again do not respond to the needs of the most vulnerable.

Changes in Transport Planning and Governance

Beyond changing the type of vehicles we use or their fuels, or the way we use them, there is also the option of implementing wider and broader changes in the way transport systems are planned and governed. As a start, this means opening up transport planning and policy to dialogue with other perspectives and traditions; for example widening the connection with the health profession or by using instruments such as Health Impact Assessment tools, or giving substantial and continued space to participatory planning experiences (Nieuwenhuijsen, 2020).

However, this approach might still be not enough when the way mobilities can and are governed is fundamentally shaped by broader societal processes and political interests. Tackling car dependency cannot fail to acknowledge the profound economic interests that are behind its perpetuation. The automotive industry has been a major political player in locking in automobility worldwide and creating a self-reinforcing system. It has strongly supported the dismantling and underfunding of public transport; it has lobbied to pressure public investment in pro-car infrastructures and devolution of public space to make room for cars; it has joined real-estate developers to favor urban sprawl; it has actively supported the development of "car culture," with advertising and marketing, and intentionally shaping consumers' choices and practices (Mattioli, 2020). As Paterson (2007) reports, automobility has become fundamental to capital accumulation and a less carbon intense world ought to profoundly rethink this relationship. A similar discussion applies to the raising economic and lobbying power of the flight industry that, as we have witnessed during the COVID-19 outbreak, has a strong influence on governments' decisions. This means that there is a need to fundamentally politicizing the discussion around transport futures, being aware of the power relations and interests that shape decisions in transport and the possibilities to shift them.

A substantial and sustained shift away from HCTS and the health impacts and inequalities associated with them, together with the changes so far mentioned, requires a profound shift in the key objective of planning and policy, as well of our economies, away from being shaped by the interests of automobility and aeromobility. As increasingly suggested in several fields of geographical, sociological, and economic research, this can be done by decoupling the idea of speed and economic growth from the achievement of human wellbeing and separating the interests of capital from the pursuit of liveable cities (D'Alessandro et al., 2020; Ferreira and Schönfeld, 2020; Raworth, 2017). Frameworks that, for example, consider transportation and mobility as a common good can be highly promising in this direction (Nikolaeva et al., 2019).

At the same time, challenging HCTS requires considering the multi-scalar, cross-border, intersectional nature of the changes we are facing. As shown in this chapter, this can be achieved by going beyond considering transport only as a matter of individual movement, technologies and infrastructure, and embracing more of a mobilities perspective which allows us to account for the societal meanings, practices and political processes linked to those movements, infrastructures and technologies. This, as suggested by sociologist Mimi Sheller (2018) in her key book on mobility justice, can allow us to integrate the understanding of what ought to be changed in HCTS with the possibility of its implementation when strictly linked to broader socioeconomic elements as well as processes of climate change and justice, migrations, social inequalities, and urban crisis.

Finally, as Sheller (2018) also suggests and as mentioned before, it is perhaps by opening up to other voices such as environmental and social movements, citizens initiatives and grassroots experiences that true change could be brought about. The climate movement as well as transport activists have been working for decades in analyzing the limitations of current mobility systems as part of a broader context of systems of capitalism, extractivism and colonialism. With a logic of self-determination and profound

respect for the ecology, they have promoted an agenda that suggests “*leaving fossil fuels in the ground, reasserting peoples’ and community control over the production of food and renewable energy, massively reducing over-consumption, particularly in the Global North, respecting the rights of indigenous and forest people, and recognising the ecological and climate debt owed to the peoples in the Global South by the societies of the Global North necessitating the making of reparations*” (Routledge et al. 2018, 79). Their experience, in participatory dialogue with the voices of citizens and minority groups, can allow planners and researchers to develop solutions to the world-dominant paradigm of the car (and increasingly the aeroplane) that are tailored to the needs of specific populations and geographies, and at the same time recognize the global effects of local choices in transport and mobilities, both for the climate and the life on the planet.

Acknowledgment

I would like to greatly thank Dr. Hannah Budnizt and Simona Sulikova for their comments and suggestions that significantly improved the manuscript.

Overview

The rapid urbanization started in the last century is still ongoing. Currently, more than half of the global population resides in cities and this proportion is projected to increase to more than two-third by 2050 (UN Department of Economic and Social Affairs, 2015). Cities are the powerhouses of innovation and wealth creation where residents usually have better access to healthcare and other facilities (Bettencourt et al., 2007). However, living in urban areas is often associated with higher exposure to a number of environmental hazards such as air pollution, noise, and heat and limited access to natural environments. At the same time, urban lifestyle is mainly associated with less physical activity and higher psychological stress (Bettencourt et al., 2007). These environmental and lifestyle factors are proposed to contribute to the existing higher prevalence of a wide range of adverse health conditions such as psychological disorders and chronic noncommunicable diseases in urban areas (Cyril et al., 2013). Natural environments, including greenspace, have been related with improved physical and mental health and wellbeing. They are also recognized as a mitigation measure to buffer the aforementioned adverse health effects of urban areas. This chapter provides an overview of (1) what urban green spaces are; (2) the potential mechanisms through which exposure to greenspace could exert health effects; (3) the health effects associated with greenspace exposure; and (4) the potentials of greenspace and transportation to promote healthy urban living.

Urban Greenspaces

US Environmental Protection Agency (EPA) has defined green space as the “land that is partly or completely covered with grass, trees, shrubs, or other vegetation” which includes “parks, community gardens, and cemeteries” (US Environmental Protection Agency, 2017). The abundance and availability of greenspace in cities could be a function of several factors from which the urban planning and climate play key roles. A survey of 386 European cities (2009), for example, showed that while there was a general north-south decreasing gradient in the proportion of the greenspace coverage among these cities, still there were greener cities in south and less

green cities in north (Fuller and Gaston, 2009). The amount of green space available to people in cities also varies considerably from, for example, 1.9 m² per person in Buenos Aires, Argentina to 52.0 m² in Curitiba, Brazil. There are many types of green spaces in cities including parks, street green, and natural green, which can be captured by different maps or remote sensing methods (Gascon et al., 2016a). Hence, the estimation of the proportion of the city covered with greenspace or the available greenspace per capita depends on the definition of greenspace and the source of available data to calculate greenspace.

Potential Mechanisms

The mechanisms underlying health effects of the exposure to greenspace are not well-established yet but reducing stress, restoring cognitive function, enhancing social cohesion/interactions, reducing sedentary behavior/increasing physical activity, mitigating the exposure to air pollution, noise, and heat, and enriching micro- and macro-biodiversity and hence environmental microbial input have been suggested to be involved.

Stress Reduction/Cognitive Restoration

An extensive body of experimental and observational evidence has established the capability of the exposure to greenspace to reduce stress and restore cognition function. The *Stress Reduction Theory* proposes that greenspace, through properties such as curving sightlines, spatial openness, and the presence of water, could induce recovery from stress and help to diminish states of arousal and negative thoughts through psycho-physiological pathways (Ulrich, 1984). *Attention Restoration Theory* postulates that contact with nature with its innately delightful stimuli could modestly invoke indirect (i.e., effortless) attention and at the same time minimize the need for directed attention that together could restore the directed attention capability (Berman et al., 2008; Kaplan, 1995; Kaplan and Kaplan, 1989). These pathways have been suggested to play important roles in the health benefits of exposure to greenspace (Dadvand et al. 2016; de Vries et al. 2013).

Mitigating Urban-Related Environmental Hazards

The impact of greenspace on air pollution is complex and context-specific. On one hand, vegetations has been suggested to reduce air pollution by direct and indirect mechanisms (Givoni, 1991). The direct mechanism is through filtering air pollutants by vegetations, mainly based on dry deposition of pollutants (both particles and gases) through stomata uptake or non-stomata deposition on plant surfaces (Akbari, 2002; Givoni, 1991; Nowak et al., 2006; Paoletti et al., 2011). The indirect effect is proposed to be through cooling effect of plants that in turn reduces smog formation (Givoni, 1991). A study on the effects of greenspace surrounding home address on personal exposure to air pollution using personal air pollution monitors reported that higher surrounding greenspace was associated with reduced personal exposure to particulate air pollution but not nitric oxides (Dadvand et al., 2012). Another study also showed that higher greenspace within and surrounding schools is associated with lower indoor and outdoor levels of traffic-related air pollutants at school (Dadvand et al., 2015). The capability of vegetations to reduce air pollution is suggested to be type-specific with trees being the most efficient and grasses being the least efficient types (Givoni, 1991). Modelling studies of the amount of air pollution removed by tree canopies in continental US (Nowak et al., 2006) and Greater London (Tallis et al., 2011) have estimated that about 1%–2% of air pollution in these areas are removed by canopies. Experimental studies on the mitigation of the air pollution by roadside vegetation have reported inconsistent results with some reports that do not support such a mitigation (Baldauf et al. 2011; Hagler et al. 2012). Simulation studies of this mitigation effect have also indicated that roadside trees are able to generate a canyon effect with higher air pollution levels on the downwind and lower air pollution levels on the upwind side of the street (Baldauf et al., 2011; Buccolieri et al., 2009). Furthermore, biodegradation of vegetation residues could generate volatile organic compounds (VOCs), a family of air pollutants with potential health effects on humans. VOCs could also participate in complex photochemical reactions with other air pollutants such as nitric oxides and ozone and engage in the generation of biogenic secondary organic aerosols (Hoyle et al., 2011; Kesselmeier and Staudt, 1999). Although the interaction between greenspace and air pollution appears to be multifaceted and complex and the available evidence on such interaction is still limited and inconsistent, the available studies evaluating the mediator role of air pollution in the observed health benefits of the exposure to greenspace are suggestive for such a mediation. For example, a recent study of the association of the exposure to greenspace on cognitive development in children estimated that up to 60% of this association could be explain by the reduction of traffic-related air pollutants by greenspace (Dadvand et al., 2015).

The capability of greenspace to reduce temperature is well established. Shading, evapotranspiration (emission of water vapor into the atmosphere), and the micro-regulation of air movements and heat exchange are among the mechanisms through which vegetations could modulate the temperature (Bowler et al., 2010). A systematic review and meta-analysis of the available studies on such effect concluded that the temperature in urban parks is on average 1°C less than that of other nongreen areas in cities (Bowler et al., 2010). Given the existence of Heat Island Effect in urban areas, the capability of the greenspace to reduce temperature is of importance for promoting resilience in cities, especially by considering the occurring changes in the global climate.

The available evidence on mitigation of noise exposure by greenspace is still limited. However, these studies are suggestive for the buffering of the noise exposure and/or reduction of noise annoyance by the greenspace surrounding the homes and also by green facades (De Ridder et al., 2004; Dzhambov et al., 2018; Gidlöf-Gunnarsson and Öhrström, 2007). Schäffer et al. (2020) investigated

the effects of residential green on noise annoyance, accounting for different transportation noise sources as well as for the degree of urbanization (Schäffer et al., 2020). Increasing residential green was found to be associated with reduced annoyance due to road traffic and railway noise, but increased annoyance due to aircraft noise.

Enhancing Social Interaction and Cohesion

A cohesive society is defined as a society that “works towards the well-being of all its members, fights exclusion and marginalization, creates a sense of belonging, promotes trust, and offers its members the opportunity of upward mobility” (Organisation for Economic Cooperation and Development (OECD), 2011). Social interaction and cohesion have been related with improved perceived general health (Kawachi et al., 2008), lower morbidity, more longevity, and reduced inequality in health (Marmot et al., 2012). The body of evidence on the relation between the exposure to greenspace and social interaction and/or cohesion is still limited; however, it is generally supportive for such a relation (Dadvand et al., 2016, 2019; de Vries et al., 2013; Maas et al., 2009a; Sugiyama et al., 2008), with a few exceptions (Triguero-Mas et al. 2015). A small number of studies have also reported that social interaction and/or cohesion could mediate the association of the exposure to greenspace with perceived general health (Dadvand et al., 2016; de Vries et al., 2013; Maas et al., 2009a).

Increasing Physical Activity

Physical activity has been postulated to act as a mediator of the health of benefits of the greenspace exposure. However, the available evidence on the potential effect of greenspace exposure on physical activity is inconsistent with a considerable heterogeneity in the reported direction and strength of associations (Bancroft et al., 2015; Lachowycz and Jones, 2011; McGrath et al., 2015). A part of this heterogeneity could be because most of these studies have not accounted for the quality aspects of green spaces while these aspects are shown to affect the use of these spaces for physical activity (McCormack et al., 2010). The few studies evaluating the mediation of health benefits of greenspace exposure by physical activity are suggestive for a modest (Dadvand et al., 2016; de Vries et al., 2013) or no (de Keijzer et al., 2018; de Keijzer et al., 2019b) mediation role of physical activity in these benefits.

Enriching Environmental Biodiversity

Plants directly modulate the microbiome present in the rhizosphere (the below-ground microbial habitat provided by plant root system) and phyllosphere (the above-ground microbial habitats provided by plants) (Berendsen et al., 2012; Vorholt, 2012), and hence could indirectly modulate the environmental microbiome to which humans are exposed. Available reports suggest that bacterial diversity in humans’ faeces decreases with the level of urbanization, which is strongly associated with reduced environmental biodiversity (De Filippo et al., 2010; Yatsunenko et al., 2012). Human microbiome including gut microbiome has been shown to interact with the host organs, regulate systemic immune response and prevent chronic inflammation (Martinez, 2014). Therefore, the ability of greenspace to enrich immunoregulation-inducing microbial input from the environment (Rook, 2013) could be a potential mechanism underlying the relation between the greenspace exposure and human health. A study in adolescents, for example, reported that living near a forest during childhood could enhance the diversity of the skin microbiome, which in turn was associated with the reduced risk of allergic sensitization later in life (Hanski et al., 2012a).

Health Benefits

Exposure to greenspace has been related with a wide range of physical and mental health benefits. This exposure, for instance, has been related with improved perceived general health, better pregnancy outcomes and lower risk of pregnancy complications, enhanced neurodevelopment in children, improved mental health and cognitive function, lower risk of a number of chronic diseases (e.g., diabetes and cardiovascular conditions), decelerated ageing, and reduced premature mortality.

Pregnancy Outcomes and Complications

The most consistent evidence on the association of maternal greenspace exposure and pregnancy outcomes has been reported for the fetal growth. Higher greenspace surrounding maternal residential address during pregnancy has been associated with increased birth weight and reduced risk of low birth weight or small for gestational age (Akaraci et al., 2020; Zhan et al., 2020). The available evidence for this association for the length of pregnancy is inconsistent. While some studies are suggestive for an increased length of gestation (i.e., reduced risk of preterm birth) associated with higher greenspace surrounding maternal residential address (Grazuleviciene et al., 2015; Hystad et al., 2014; Laurent et al., 2013; Nichani et al., 2017), other studies have not supported this association (Agay-Shay et al., 2014; Dadvand et al., 2012a, 2012b). A limited number of studies have also evaluated the association between maternal greenspace exposure during pregnancy and the risk of pregnancy complications such as gestational diabetes and pregnancy-induced hypertensive disorders including preeclampsia. Although a recent systematic review and meta-analysis of the available literature (Zhan et al., 2020) did not find any statistically significant association between greenspace exposure and pregnancy complications, but these studies were generally supportive of a protective association.

Neurodevelopment in Children

The “biophilia hypothesis” proposes that humans have evolutionary bonds to nature (Kellert and Wilson, 1993; Wilson, 1984). Accordingly, contact with nature including greenspace is postulated to have a crucial role in the neurodevelopment of children (Kahn and Kellert, 2002; Kellert, 2005). Earlier experimental studies have shown that spending time and playing in greenspaces could, in short-term, reduce severity of symptoms and improve attention in children with attention deficit-hyperactivity disorder (ADHD) (Kuo and Taylor, 2004; Taylor et al., 2001; Taylor and Kuo, 2009; van den Berg and van den Berg, 2011). More recently, observational epidemiological studies have reported that higher residential surrounding greenspace and more time spent playing in greenspaces in long run could reduce risk of behavioral and emotional problems including ADHD (Amoly et al., 2014; Markevych et al., 2014b) and enhance cognitive development including attention and working memory (Dadvand et al., 2015, 2017; Wells, 2000).

Cognitive Function in Adults

In adults, the available evidence for the association of exposure to greenspace with cognitive function is still scarce and mainly deals with effects of visual access to greenspace on cognitive function (de Keijzer et al., 2016). These studies, all cross-sectional, are suggestive for improved cognitive functions including better direct attentional capacity and lower concentration problems associated with the visual access to greenspace (de Keijzer et al., 2016).

Perceived General Health

Exposure to greenspace has been consistently related with improved perceived general health in adults (Gascon et al., 2015) and self-satisfaction in children (Dadvand et al., 2019). Studies have shown that improved mental health and social cohesion and, to less extent, enhanced physical activity are among the main mechanisms underlying this association (Dadvand et al., 2016; de Vries et al., 2013).

Mental Health

The effect of exposure to greenspace on mental health is one of the most established health effects of this exposure. Higher exposure to greenspace has been associated with improved mood and lower risk of psychological distress and psychiatric conditions such as depression and anxiety and less likelihood of use of psychiatric medicine (Gascon et al., 2015; Mygind et al., 2019; Vanaken and Danckaerts, 2018).

Other Noncommunicable Diseases

The available evidence on the impacts of greenspaces on noncommunicable diseases other than asthma and allergy is still limited but is suggestive for a beneficial impact. More exposure to greenspace has been associated with lower risk of cardiovascular conditions, diabetes, and lower back pain in adults (Dalton et al., 2016; Maas et al., 2009b). In children, this exposure has been associated with lower blood pressure (Markevych et al., 2014a) and lower blood glucose level and less risk of hyperglycaemia (Dadvand et al., 2018).

Ageing

The available evidence on the potential effects of long-term exposure to greenspace on ageing is accumulating and is suggestive for the capability of this exposure to promote healthy ageing and improve mental and physical health and wellbeing of elderly (de Keijzer et al., 2020). Specifically, long-term exposure to greenspace has been associated with better cognitive function, physical capability, mental health and perceived wellbeing and lower risk of morbidities (de Keijzer et al., 2020). For example, a series of recent longitudinal studies conducted in the ageing Whitehall II cohort has shown that higher residential surrounding greenspace is associated with decelerated cognitive ageing (de Keijzer et al., 2018) and physical functioning decline (de Keijzer et al., 2019b) and a reduced risk of incident metabolic syndrome (de Keijzer et al., 2019a) in elderly.

Mortality

Two systematic reviews and meta-analyses of the available literature on the impact of exposure to greenspace on mortality have found that higher residential surrounding greenspace is associated with reduced all-cause premature mortality as well as cardiovascular mortality (Gascon et al., 2016b; Rojas-Rueda et al., 2019). More physical activity, lower exposure to air pollution, enhanced social cohesion, and improved mental health have been reported to mediate the association between exposure to greenspace and mortality (James et al., 2016).

Health Risks

In addition to the health benefits, green spaces could also potentially induce a number of adverse health outcomes including asthma and allergic conditions, increase exposure to pesticides, host reservoirs and vectors of infectious diseases, and enhance the risk of accidental injuries.

Asthma and Allergy

The available evidence on the impact of exposure to greenspace on asthma and allergic conditions in children is inconsistent. While some studies have related higher residential surrounding greenspace with increased risk of asthma and allergic conditions (Andrusaityte et al., 2016; DellaValle et al., 2012; Lovasi et al., 2013), others have not found such a relation or have even reported protective associations (Hanski et al., 2012b; Hind et al., 2017; Lovasi et al., 2008; Maas et al., 2009b; Pilat et al., 2012). The type of greenspace and the bioclimatic properties of the study region could explain, in part, such an inconsistency. One study, for example, has reported that while urban parks were related with higher risk of asthma and allergic attacks, natural greenspaces (e.g., forests) did not show such a relation (Dadvand et al., 2014). Another study conducted in seven birth cohorts in Australia, Canada, Germany, Netherlands, and Sweden, showed a notable between-centre heterogeneity in terms of the direction and strength of associations (Fuentes et al., 2016). A recent systematic review of the available evidence has suggested a potentially protective association of the greenspace exposure with asthma in children (Hartley et al., 2020).

Pesticide Exposure

Application of pesticides in green spaces, especially in agricultural lands, could expose individuals living nearby these spaces or those who use these spaces to these chemicals. This exposure, in turn, could lead to a range of health outcomes including cancers as well as adverse conditions in nervous, reproductive, endocrine, and immune systems (Blair et al., 2015).

Vector-Based and Zoonotic Infections

Green spaces could host reservoirs and vectors of infectious diseases, which could increase the risk of vector-borne diseases transferred by mosquitoes (e.g., Dengue fever or malaria), ticks (e.g., Lyme disease and tick-borne encephalitis), or sandflies (e.g., leishmaniasis) (WHO Regional Office for Europe, 2016). Exposure to animal faeces in green spaces could also induce zoonotic infections such as toxocariasis or toxoplasmosis (WHO Regional Office for Europe, 2016).

Accidental Injuries

Users of green spaces, especially children, could experience accidental injuries such as falls or drowning while they are in these spaces. However, at population level, the injuries that occur in green spaces account for a very tiny proportion of accidental injuries (WHO Regional Office for Europe, 2016) and they are to a large extent preventable through proper design of these spaces and putting in place preventive measures.

Greenspace, Transportation, and Healthy Urban Living

Commuting

Commuting routes with natural features could promote walking or cycling for commuting. Moreover, commuting through green environments could have mental health benefits as exposure to greenspace can reduce stress and improve mental health. In one of the few available studies, Zijlema et al. (2018) evaluated the association between natural, mainly green, environments and commuting, whether active or not, and the association between commuting (through green environments), whether active or not, and mental health in four European cities in Spain, the Netherlands, Lithuania and the United Kingdom (Zijlema et al., 2018). Data on commuting behavior (active commuting at least one day/week, daily green environment commuting) and mental health were collected through questionnaires. Adjusted multilevel analyses showed that daily green environment commuters were more often active commuters. Furthermore, there was no association between active commuting and mental health, but daily commuters through green environments had on average a 2.74 (95% confidence intervals (CIs): 1.66, 3.82) point higher mental health score than those not commuting through green environments. The association with mental health was stronger among active commuters (4.03, 95% CIs: 2.13, 5.94) compared to nonactive commuters (2.21; 95% CIs: 0.90, 3.51) when daily commuting through green environments. Briefly, the study showed that Daily commuting through green environments was associated with better mental health, especially for active commuters. But also that daily commuters through green environments were more likely to be active commuters. Active commuting itself was not associated with mental health. These findings suggest that cities should invest in green commuting routes for cycling and walking.

Green Replacement

Given the many benefits of the exposure greenspace, the health and wellbeing of residents in urban areas, where there is often a lack of greenspace, can be improved through increasing the amount, availability, and quality of green spaces (Nieuwenhuijsen et al., 2017; van den Bosch and Nieuwenhuijsen, 2017). Cities can be made healthier and more equitable for people, not by painting trees on walls, but by having a park near where people live, planting trees in the streets, and introducing urban gardens. Urban gardens may have additional benefits in terms of social cohesion, local food production and economy and, if done at a

sufficiently large scale, can contribute to the sustainability and self-sufficiency of cities. Most cities need more parks, which can also become a part of their identity and attraction. Also, green roofs and walls may transform the city, not only in terms of resilience but also in terms of visual attractiveness. Our current cities are too car dominated, and car infrastructure such as roads and parking take up much space that can be, otherwise, used for developing green spaces. Reducing space for cars and the number of cars could have the additional advantage that people have to switch to public and active transportation and thereby reducing the major urban-related environmental hazards (i.e., air pollution and noise) in cities and increasing physical activity in citizens (Nieuwenhuijsen and Khreis, 2016). New urban concepts like the Superblocks (Barcelona), car free cities (Hamburg) or the 15-min city (Paris) can create space for greenspace and a healthier transport environment that not only are more sustainable and liveable but also healthier (Nieuwenhuijsen, 2020). Although greening our cities is not the only solution to improve the health and wellbeing of residents, it can certainly make an important contribution, which is being increasingly recognized through new studies assessing the health impacts of urban and transport planning (Nieuwenhuijsen, 2020).

Final Remarks

Although greenspace can result in great health benefits and many cities are bringing in more greenspace, the magnitude of the link between transport, greenspace and health has not been well explored and needs further work. There are still questions such as for example what type of, how much and where do we exactly need more greenspace to get the greatest benefits. However, this should not stop us from greening of cities and creating greener environments for transport, particularly for active commuting, which is the most sustainable and healthy way of mobility.

From Access to Healthiness

From its source Latin *accedere*, the assimilated form of *ad* and *cedere*, access means “to approach.” It conveys “habit or power of getting into the presence of someone or something.” The contemporary meaning is different, but not too far from the origin. Access means freedom (Access, 2020). It offers neither what people will do nor what people want to do, rather what people could do. Access is a product of mobility and place, and immediately relates to the transport network and the relative location of human activities and housing. Mobility means the ability to move easily. It reflects network speed or travel time, and is complementary to access, rather than competitive. Mobility improvements can contribute to improving access. Yet mobility is just a fraction of the access concept. An illustrative example suffices: I draw it from my experience living in Chicago, the third-most-populous city in the United States, and the Starkville, a marquee American college town located in east-central Mississippi. Driving 30 min from downtown Starkville, a traveler can almost cover the entire city, but reaches only two Starbucks Coffeehouses. Conversely, while driving 30 min in downtown Chicago does not get you far, you can reach more than a dozen Starbucks Coffeehouses. This opens more opportunities including jobs, groceries, health care, education, and recreational facilities with a direct and indirect influence on health. Fig. 1 depicts how access to opportunities affects maintaining a healthy life style and well-being. Research declares access to hospitals (Love and Lindquist, 1995), primary care physicians (Schuurman et al., 2010), pharmacies (Cooper et al., 2009), grocery stores (Zenk et al., 2005), parks (Roemmich et al., 2006), trails (Wolf and Wohlfart, 2014), and playgrounds (Smoyer-Tomic et al., 2004) contribute to personal well-being.

Should not we deliver access to opportunities equitably? From the Civil War to the Civil rights movement, the signing of the Treaty of Paris 1783 to pulling out of the Paris Agreement in 2017, the United States has spent much of its existence grappling with the problem of equity. Throughout the 20th century, minority groups and low-income populations fought for equitable access to health care, jobs, education, and public transit. In 1955, African Americans in Montgomery, Alabama began The Bus Boycott, which ended up going before the Supreme Court and integrating transport across the United States. The Bus Boycott was the first ripple in a wave that led to the signing of the Civil Rights Act in 1964, under which, “All persons shall be entitled to the full and equal enjoyment of the goods, services, facilities, and privileges, advantages, and accommodations of any place of public accommodation. .. without discrimination or segregation on the ground of race, color, religion, or national origin.” In the 1980s, the fight for equity turned toward the environment, as studies commenced identifying poor and nonwhite residential communities, mainly in the South, as more likely to house hazardous waste facilities. However, another decade passed until this uneven dispersal of hazardous materials began to be addressed. In 1994, President Clinton signed Executive Order 12898 into law, ordering Federal agencies to prioritize environmental justice for poor and minority communities. The quest for justice escalated on April 15, 1997, when the U.S. Department of Transportation released DOT Order 5610.2 that reaffirmed its responsibility to bring justice to the transport industry.

Though history has made progress in the equity movement, there is still a sharp divide between income classes, minorities, the elderly, and gender in terms of equity of access to opportunities (Ermagun and Tilahun, 2020). For many this means the working poor, African Americans, Hispanics, the elderly, and people with disabilities are left in communities that have been segregated into the “haves”: affordable and efficient transport to work, health care, healthy food, education, and recreation, and the “have nots.” Transport authorities, indeed, have failed to equitably distribute transport access and have worked for the benefit of car owners. This biased approach begets transport-related social exclusion. This is a process by which people are limited to participate in social activities, in part due to either the lack of access to opportunities or mobility impairment (Preston and Rajé, 2007). Regardless of the opportunity, transport-related social exclusion leads to diminished levels of well-being particularly for underserved and underrepresented groups as illustrated in Fig. 1. This highlights the concern of transport access as a social equity issue.

Access-related equity is split up into (1) equity and social class and (2) equity and mobility need (Litman, 2002). The former aims to disclose the disparity of access in groups that differ in social, demographic, and economic characteristics. How access is distributed among low- and high-income groups targets this access-related equity category. The latter aims to show to what extent access meets the needs of the people with mobility impairments and special constraints. This category targets how access is provided for people

Figure 1 Direct and indirect relation between transport access to opportunities and health.

with disabilities. Access-related equity has been discussed at some length in the transport literature, leaning more toward employment opportunities (Borowski et al., 2018; Pyrialakou et al., 2016; Sanchez, 1999; Thakuriah and Metaxatos, 2000). Little is known about the equity of access to health-related services, despite the fact that transport access is often perceived as a major barrier to medication and health care access. A 2005 study estimates Americans who miss or delay nonemergency medical treatment every year due to transport barriers at 3.6 million (Wallace et al., 2005).

Access-Related Transport Barriers to Healthcare

It is conceived that inequity of access to health-related services is a consequence of several factors operating at a number of different levels as highlighted in Fig. 2. These factors range from socioeconomic and demographic characteristics of individuals to those operating at mobility and place levels. Inequity of access to health-related services is often reflected either as a lack of vehicle access or mobility impairment to reach health care facilities because of social status or a lacking access to health care facilities as a product of mobility and place.

Research unanimously indicates that a lack of vehicle access or mobility impairment is negatively correlated with the utilization of health care. Arcury et al. (2005) surveyed 1059 people from 12 counties in North Carolina. Of the respondents, consisting of 948 nonminority and 111 African Americans, individuals who had a driver's license were over two times more likely to visit a doctor regularly versus those who do not have a driver's license. Individuals who had friends and family they could rely on for transport

Figure 2 Determinants of inequity of access to health-related services.

Table 1 Summary of studies exploring equity of transport access to health care

Article	Area	Access measure	Travel threshold	Travel mode	Cohorts
Ermagun and Tilahun (2020)	US	Cumulative opportunities	30 min	PT	Minority, low-income, elderly, disabled, low-educated, carless
Pu et al. (2020)	Congo	Raster-based accessibility	2 h	W, M, PT	General population
Boisjoly et al. (2020)	Canada	2SFCA	45 min	PT	Vulnerable
Tao and Cheng (2019)	China	2SFCA	124 min	PT, PC	Elderly
Campbell et al. (2019)	Nairobi	Gravity	60 min	W, P, PC	Low and middle incomes
Kelobonye et al. (2019)	Australia	2SFCA	15 min	PT, PC	Residents location
Guimarães et al. (2019)	Brazil	Focus groups	–	W, PT	Low incomes
Mayaud et al. (2019)	Cascadia	Catchment area	30 min	PT	Low incomes, elderly
Madill et al. (2018)	Australia	Travel time	–	PT, PC	Residents location
Agbenyo et al. (2017)	Ghana	Travel distance	5 km	W, M, B, PT	General population
Higgs et al. (2017)	UK	2SFCA	15 min	PT, PC	Elderly
Ahern and Hine (2015)	Ireland	Focus groups	–	PT, PC	Elderly
Wang (2011)	Canada	2SFCA	11 min	PC	Immigrants

Paez et al. (2010)	Canada	Cumulative opportunities	–	PC	Elderly
Dai (2010)	US	2SFCA	15, 20, 25, 30 min	PC	African American segregation
Lovett et al. (2002)	UK	Travel time	0–40 min	PT, PC	Residents location

2SFCA, two-step floating catchment area; B, bike; M, motor; P, paratransit; PT, public transit; W, walking; PC, private car.

were more than 1.5 times as likely to see the doctor as those without a ride. Yang et al. (2006) conducted a cross-sectional study of low-income families, all of whom have State Children's Health Insurance Programs for their children, to determine what factors caused a caregiver to keep or miss an appointment. Of the caregivers who canceled their appointment, 50% said a transport issue, such as not having a ride, not having a public transit option, or traffic as the reason for canceled appointments.

Lack of access to health care facilities is often explored through the analysis of geographical location of people and their distance or travel time to health care facilities. The results are mixed. Most research shows rural patients have greater transport barriers to health care facilities than urban patients and highlights distance is a barrier. Few studies declare that there is no significant relationship between health care utilization and either geographical location of people or their distance to health care facilities. Blazer et al. (1995) collected a stratified random sample of 4162 residents of one urban and four rural counties of North Carolina, which was representative of more than 28,000 residents 65 years of age and older. They found that rural residents were more likely to use alternative medical facilities or to forgo treatment until it was absolutely necessary due to problems being transported to a medical facility. Participants cited the cost of traveling to the health care facility and, in many cases, having to depend on friends and family to transport them, was an influential factor. Probst et al. (2007) drawn data from 2001 US National Household Travel Survey to analyze effects of residence and race on burden of travel for care. They found rural residents, on average, traveled about 15 km (9 miles) further for care than urban residents, taking about six additional minutes to complete their trip. In a study of special needs families, Skinner and Slifkin (2007) showed children in rural areas were more likely than urban children to miss a treatment or appointment due to lack of transport to a care facility. Using a subsample of 102 family caregivers from 31 states, Kruzich et al. (2003) highlighted that since clinics emphasize parental participation in the therapies, facilities that are further away require the caregiver to take time away from their job which in turn increases their financial burden. In a survey of 781 diabetic adults, Littenberg et al. (2006) discussed that the farther the patient lives from their medical facility, the less likely they are to receive insulin treatment. This strongly affects diabetics who live in rural regions quality of life, as it becomes harder to control glucose levels. Strauss et al. (2006) had similar findings performing a cross-sectional analysis of 973 adults with diabetes in Vermont, New Hampshire, and northern New York. They pinpointed for every 35 km (22 miles) a patient would have to drive, their glucose measure increases by 0.25%.

Transport barriers disproportionately affect different demographic and socioeconomic cohorts. Minority and low-income populations, the elderly, disabled, low-educated, female, and people without a car face transport barriers more than their counterparts. Probst et al. (2007) showed African Americans were more likely than whites to have trips for care that required more than 30 min of travel, even though the distance traveled is much shorter. They posit this is because African Americans are more likely to rely on public transit as their main source for transport. Wallace et al. (2005) estimated the transport-disadvantaged population using data from (1) the Bureau of Transportation Statistics, (2) U.S. 2002 National Health Interview Survey, and (3) Medical Expenditure Panel Survey. They concluded that the transport-disadvantaged population are poorer, older, female, minority, and less educated. In addition, they showed children who lack access to medical care due to transport barriers are more concentrated in urban areas and people with chronic conditions and multiple diseases experience greater difficulty in accessing health care due to the lack of nonemergency medical transport. Conducting a telephone survey among 2097 rural community-dwelling elders in West Texas, Borders (2004) found that Hispanic elders are more likely to live out in rural areas and be more dependent on family for transport. This not only limits how often they can see their doctor but also the privilege of seeing the same doctor for continuing care.

Equity of Access to Health Care

The well-being of individuals, as alluded to in [Fig. 1](#), is associated with access. An underlying tone to the access to health care is the socioeconomic and demographic attributes amongst the disadvantaged and affluent groups in the society. Research has focused on how access to health care is distributed among different sociodemographic groups. [Table 1](#) lists the related research. It is not the intent of the summary of literature presented in [Table 1](#) to be all inclusive. Rather, its purpose is to provide a broad range of research time frames, locations, modes of transport, access thresholds, and research methodologies used to measure the equity of access to health care over the past 20 years. The geographical scope of studies specifies that the equity of access to health care is a need perceived around the globe spanning from Asia ([Tao and Cheng, 2019](#)), Africa ([Harris et al., 2011](#)), and Europe ([Higgs et al., 2017](#)) to America ([Mayaud et al., 2019](#)), and Australia ([Madill et al., 2018](#)). Research studies the equity of access to health care objectively by measuring access to health care ([Boisjoly et al., 2020](#); [Campbell et al., 2019](#); [Ermagun and Tilahun, 2020](#); [Kelobonye et al., 2019](#)) or subjectively by conducting focus groups or using national and local surveys ([Ahern and Hine, 2015](#); [Guimarães et al., 2019](#); [Harris et al., 2011](#)).

Measuring access to health care methods ranges from abstracted Euclidean or Manhattan distance to two-step floating catchment area and gravity measures. [Boisjoly et al. \(2020\)](#) quantified access to healthcare services by public transport in eight metropolitan regions of Canada using a two-step floating catchment area method. The study areas covered different population sizes from small to large regions, selected based on data availability with health care data from Canadian Institute for Health Information and the transport data from the General Transit Feed Specification. They showed individuals residing in large metropolitan areas were subjected to low levels of access to health care facilities due to spatial dispersion of the areas that affect transport. [Mayaud et al. \(2019\)](#) compared the equity of access to health care facilities by public transit in Portland, Seattle, and Vancouver, located in the Cascadia region. A catchment analysis was performed to analyze the socioeconomic makeup and determine access to health-related facilities. The findings indicated that Portland displays the highest inequity in health care facilities access, and Vancouver the least, owing to Vancouver's relatively compact geographic area and high population density. Over 75% of seniors are socially excluded from hospitals and over 50% from clinics in Portland, compared to 30% and 3%, respectively, in Vancouver. The inequality of access to health care facilities also exists among low-income neighborhoods in all three cities. This translates into proportionally higher transport costs for low-income area residents compared with high-income area residents. They argued access to health facilities in Portland are more centralized due to the setup of its public transport network. For Seattle and Vancouver, however, the public transport network is setup to distribute access more evenly. [Higgs et al. \(2017\)](#) argued that access to general practitioners (GP) is linked to the availability of transport amongst other problems such as socioeconomic factors, community isolation, and spatial distribution. Individuals who lack vehicle ownership, are poverty stricken, or are elderly rely on the use of public transport to access healthcare facilities. Using the South Wales case, they employed Enhanced Two-Step Floating Catchment Area techniques for measuring access GP surgeries by car and bus within a 15-min threshold time. Evidence showed there was a negative correlation between the percentage of persons aged over 65 years and distance to GP by either car or bus. For every percentage increase in persons aged over 65 years the distance to GP decreases by 0.09 km and 0.13 km by car and bus, respectively. There was also a negative association between percentage of persons aged over 65 years and the number of GPs located within a 15-min threshold traveling by car, but the association was not significant when traveling by bus. While mode of travel was an important consideration for determining access, the study suggested other factors provide more precise means to measure access—distance, density, and ease of access.

Measuring access to health care is often limited to the number of cumulative health care facilities reachable under an impedance function as the measure of access. This immediately ignores “trips not taken” due to barriers, which might be captured by subjective studies. Measures used in quantifying the equity of access to health care are not satisfactory tools to detect trips not taken and barriers impacting the actual behavior of individuals. In contrast, focus groups and designed surveys afford explanatory information about how transport, socioeconomic, and demographic barriers exclude vulnerable populations from reaching to health care facilities even if they are physically located in their catchment areas. [Guimarães et al. \(2019\)](#) developed a conceptual framework on health care access needs, which identified the land use interaction and interconnectivity between transport and health care as a meso-level satisfier. Transport elements were comprised of safety, comfort, speed, cost, information, public transit stops and routes, public transit service times, public transit frequency, and public transit punctuality. Health care elements were comprised of information, location, opening times, waiting times, adequacy, quality of care, referral system, coordination, and continuity. They used focus groups as a medium to collect information of 114 residents in 12 low-income neighborhoods in São Paulo, Brazil. The outcome of the focus group led to the frequency of the themes considered relevant to the participants from the standpoint of access to health care: proximity and remoteness, walking safety, public transport services, personal security, and quality of health care services. Respondents reported concerns of deficiencies and inadequacy of the transport facilities with issues not limited to lack of sidewalks, uneven walking surfaces, narrow pedestrian paths, and lack of traffic signals. These poor designs pose limitation to the safety of all individuals using the infrastructure—young, old, and disabled. Residents of low-income areas rely on public transit systems to get around for different purposes and are fully aware of the issues of mobility and access that arises. Lacking car ownership, people are left to grapple with the issues of availability, affordability, comfort, reliability, and overcrowding. Issues of crime and violence are dominant in low-income communities as revealed from the focus group. Residents are left concerned about their personal security especially for pedestrians who fear assault and public transit users who fear sexual assault as the crimes are dependent on the travel mode.

Conclusion

Access is the ease of reaching valued destinations by different modes of travel to accomplish the desired services and activities. As the ultimate goal in transport planning, access has a wide variety of factors that can affect it not limited to mobility, proximity, transport system connectivity, affordability, convenience, and social acceptability (Litman, 2008). The issues of transport are not just a mere dichotomy between health care and transport, or a trichotomy of places, socioeconomic, and demographic attributes. Barriers to health care are not a standalone issue. Individual level characteristics, mobility, and land use attributes affect access to health care. How individuals get access to health care is linked to how they get to these facilities. Most are not able to afford using private modes of travel and revert to public transit or walking. Both travel modes have challenges related to them, with more pockets in rural areas and areas with a higher percentage of minority, low-income families, the elderly, people with disability, and low-educated people. Individual level characteristics could affect how the marginalized live and survive. The challenges faced by the marginalized are greater compared to the affluent.

In the development of policy or legislation, vulnerable people were never completely ignored, but their needs were never taken seriously. They have been condemned to have a decent “level-of-access.” The initial stages of planning of cities and transport are critical to ensuring vulnerable people are accounted for to enable access. Policies should enable connected land use, transport, and the service system to allow for better access to much needed health and wellness services. Through studies, policies can be revised and recommendations can be made for improvements for planning transport to improve health care access for vulnerable people. It, however, must be noticed that providing access is a wicked planning problem and the contrast between the haves and the have nots often persists. First, there are mismatched incentives between transport networks and land regulations. There is no guarantee that the efficient choice of transport networks and land is harmonious. Second, transport networks are often regulated by the public sector, while the location of human activities is owned by the private sector. As transport networks are not built for free, the public sector might pursue investments that provide high access per dollar returns. If this happens, investments do not necessarily benefit people equitably. The first chapter of “A Political Economy of Access” notes this trade-off through the lens of equity and efficiency of access (Levinson and King, 2019).

It also must be noticed that the noisy confusion in the equity of access debates is in part due to understanding equity as the equal distribution of physical access to health care. However, what needs to be delivered equitably is not just the number of cumulative health care facilities reachable under an impedance function as the measure of access, but the means to lift barriers in the ability to reach health care facilities. This issue does not necessarily need to be tackled by changes in transport infrastructures. Supporting online consultations delivery initiatives or distributing and stocking healthy foods in local shops are efficient solution examples to lift transport barriers, rather than investing in transport infrastructure. The former initiative eliminates the need of many patients to travel to health care facilities and the latter initiative eliminates the barrier of distance to healthy foods for people with low mobility.

Overall, the intent here has not been to provide techniques to solve the actual problem of transport access to healthcare. Rather, the intent has been to emphasize that the problem exists, even in areas which involve some planning, and to distinguish facts from values. The intent has been to help city authorities, planners, and practitioners work with facts to effectively reach their values.

Introduction

“Social exclusion” is a term first coined by Lenoir (1974) in France. It describes the conditions that some people find themselves in, living outside society and so not able to enjoy many of the opportunities that it offers in terms of material goods and support, when required, in return for contributing to it through labour and taxation. Society offers the opportunity to participate in activities to help maintain good health. It also provides facilities to aid recovery from illness, and support when ill. Those who are excluded from society may not be able to enjoy such benefits and so may have poorer health than other people. Part of the reason for this is that it is necessary to travel to receive some medical treatment, and to participate in some healthy activities. Those who are excluded from society may not have access to travel facilities for a variety of reasons. The purpose of this article is to examine evidence that underpins the relationship between social exclusion and health and the role that transport plays in this.

The Nature of Social Exclusion

There have been a number of reports and academic papers about social exclusion, and they use various definitions of social exclusion. O'Donnell et al. (2018) list nine different definitions of it and six of its converse, social inclusion. They point out that some focus on the problems associated with not being included in society while others mention the various aspects of life that people are excluded from, such as a range of employment and education opportunities. The definitions are at various levels of abstraction and consider various levels at which social exclusion can operate. The common point about all the definitions is that they reflect the multi-dimensional aspect of social exclusion. Kenyon et al. (2002) list the following dimensions:

- Economic
- Societal
- Social networks
- Organized political (ability to influence decision making at an organised level)
- Personal political (ability to make decisions over own life)
- Personal
- Living space
- Temporal
- Mobility

For each of these, they list the potentially exclusionary factors.

In this article, the definition used by the authors of the various sources of evidence will be accepted as being appropriate for the issues being addressed, but it should be borne in mind that there may be subtle differences that reflect the context of the work, and possibly, the disciplinary background of the authors. The key point is that people who are socially excluded do not have the ability, opportunities and resources to participate fully in the opportunities offered by society that the individuals wish to take advantage of (or would if they were aware of them).

The Relationship Between Social Exclusion and Health

Article 12 of the United Nations International Covenant on Economic, Social and Cultural Rights says “The States Parties to the present Covenant recognize the right of everyone to the enjoyment of the highest attainable standard of physical and mental health” (United Nations, 1966). While everyone may have the right to good health, it is quite likely that some people are unable to achieve it because they cannot access the facilities and opportunities to enable them to do so because they are excluded from society.

The World Health Organization (WHO) set up the Social Exclusion Knowledge Network (SEKN) that produced a report (Popay et al., 2008) that considered the nature of social exclusion and developed a conceptual framework for understanding social exclusion in the context of health inequalities. The report also examined evidence about some existing policies and actions being used to address social exclusion around the world. The report describes how social exclusion processes lead to health inequities as a result of a continuum of inclusion/exclusion characterized by inequalities in:

- Access to resources (means that can be used to meet human needs)
- Capabilities (the relative power people have to utilize the resources available to them)
- Rights

These operate across four dimensions: economic, political, social, and cultural. The report argues that social exclusion influences health directly, through its manifestations in the health system, and indirectly, by affecting economic and other social inequalities that influence health. These inequalities then contribute to social exclusion processes, creating a vicious circle.

The World Health Organization (2010a) argues that health systems have a key role in addressing the relationship between poverty, social exclusion and health through four mechanisms: financing, stewardship, service delivery and resource generation. Financing helps by ensuring universal availability of the services, stewardship involves engaging with other sectors that influence health, service delivery helps to ensure that the health needs of socially excluded people are targeted, and resource generation contributes to health equity by ensuring that education of future health and medical professionals includes understanding of the health needs of people who are socially excluded and how these can be addressed.

In 2008, the Tallinn Charter (World Health Organization, 2008) was endorsed by European ministers of health. It is a commitment by the 53 Member States of the WHO in Europe to ensure that health systems pay due attention to the needs of vulnerable people. Not only did it contain a commitment to providing good quality health services for all, including vulnerable people, in response to their needs, it also acknowledged the need to enable people to make healthy lifestyle changes. This implies that people who are socially excluded are not only entitled to access good quality services, but also, have the opportunity to have healthy lifestyles, both positive, such as through health enhancing physical activity, and by avoiding factors that can adversely affect health. The evidence below suggests that this is not always the case. The recognition of the commitment across Europe to adapt health systems to address the needs of people who are socially excluded is illustrated by the twenty-two cases studies described in a report by the World Health Organization (2010b).

Further evidence of the international recognition of the relationship between social exclusion and health is presented by van Bergen et al. (2019) who examined 22 case studies of the links in EU and OECD countries. They found an association between high levels of social exclusion (or low levels of social inclusion) and adverse mental and general health. For physical health, the evidence was unclear. They also looked at the evidence for people in groups at high risk of social exclusion (adults in HIV treatment, problematic drug users, and single mothers) and found an association between high social exclusion (or low social inclusion) and adverse mental health, but not for physical and general health.

The links between social exclusion and health in healthcare settings in have been examined in a scoping study by O'Donnell et al. (2018) who reviewed 22 instruments (questionnaires) used to measure social exclusion or inclusion. The focus of 19 of these was mental health. In all cases, the instruments included “social networks” and in 17 cases they also included “community.”

Some studies have focused on particular groups who may be at high risk of social exclusion. Watson et al. (2016) looked at health and social exclusion for homeless people in Ontario, Canada, by conducting interviews with 21 people who did not have a permanent residence that they could return to when they chose. Several themes emerged from the analysis in three domains: social environment, health behaviors, and health status. The three domains were interwoven. When participants did not feel supported by those around them in their “social environments,” it was difficult for them to feel motivated to practice “healthy behaviors.” The behaviors that helped participants cope with possible social exclusion, homelessness and health changes might lead to a decline in “health status.” Changes to participants’ behaviors and social environments could influence their health status, and vice versa.

Sacker et al. (2017) used the UK Household Longitudinal Study to examine social exclusion and health among older people who are another group who are at risk of social exclusion. They found that among older people in the United Kingdom, poor health is associated with greater social exclusion and, in turn, social exclusion is linked to health decline. They also found that use of a car, mobile phone and the internet are factors that protected older adults in poor health from social exclusion and suggest that designing age-friendly hardware and software might help support social inclusion in later life and have public health benefits.

Transport in the Relationship Between Social Exclusion and Health

The evidence discussed earlier has demonstrated the existence of a relationship between social exclusion and health. Most of the empirical evidence is cross-sectional and so cannot demonstrate the direction of causality. It can be hypothesized that the

relationship works both ways: people who are socially excluded have poorer access to healthcare facilities which lead to poorer health, for example, and some people who have poor health may not be able to work sufficiently to earn enough income to maintain a reasonable standard of living and so their standard of living declines and they finish up excluded from society.

An intermediary factor in the relationship may be transport because travel is often required to access healthcare and to maintain a healthy lifestyle, and those in poor health may have limited access to travel facilities to enable them to remain within society. These issues will be considered further.

Social Exclusion and the Ability to Travel

Some of the characteristics of people who are socially excluded may affect their access to travel:

- **Income:** People with low incomes travel less than richer people. This is illustrated by evidence for England in 2018, where people in the top income quintile travelled an average of 14,810 km a year, and those in the lowest quintile had an average of 6,534 km (Department for Transport, 2019a). This may be partly because poorer people have lower car ownership: in England 54% in the lowest income quintile owned one or more cars compared with the top highest quintile with 87%. They may also have more difficulty paying public transport fares. Horten and Reed (2010) showed that government spending in Britain on transport is strongly biased towards higher income groups because they are more likely to use road and rail than poorer people and they are the modes that tend to attract government expenditure rather than buses.
- **Disability:** This is illustrated by the fact that in England in 2018, the 9% of people aged 16+ with mobility difficulties made an average of 603 trips a year while those without a mobility difficulty made 1049 trips on average (Department for Transport, 2019a).
- **Age:** Older people travel less than younger people because they are more likely to have given up driving, have greater difficulty walking, and difficulty climbing stairs which may make using public transport more difficult and these problems tend to increase with age (Mackett, 2014b, 2017). Travel may be difficult for some young people who cannot afford to learn to drive or afford bus fares and so become excluded from the job market and leisure facilities (pteg, 2010). Younger children may live with a single parent who is employed and so unable to take them or unable to afford the cost of travel to after-school activities (pteg, 2010).
- **Gender:** More men than women hold driving licence: in England in 2018, 81% of males aged 17+ held a licence compared with 70% of females (Department for Transport, 2019a), but more women than men said that they felt unsafe using buses (Department for Transport, 2014).
- **Ethnicity:** In England, members of black and Asian ethnic groups make over 15% fewer trips and have lower car ownership than white people (Department for Transport, 2019a).

Barriers to Travel

Part of the reason for the differences discussed earlier is that barriers to travel exist and these affect some socially excluded people more than others. Some examples are shown as:

- **Cost:** As implied earlier, those with lower incomes travel less than wealthier people partly because of the cost of travel. One in four unemployed people say that their job search is inhibited by the cost of travel to interviews (Social Exclusion Unit, 2003), which means that the chances of obtaining employment are lower.
- **Availability of transport:** As discussed earlier, poorer people have less access to car than those who are wealthy and so are more dependent on public transport. It takes much longer to reach key services (centers of employment, shops, schools, and medical services) for those traveling by public transport and walking compared to those using a car, particularly in rural areas in England (Department for Transport, 2019b).
- **Psychological barriers:** Some people with mental health conditions are so anxious about using some modes of travel that they cannot use them (Mackett, 2019).
- **Physical barriers:** Sometimes small physical barriers such as characteristics of the footway and road crossings can prevent some less mobile older and disabled people from traveling (Titheridge et al., 2009).
- **Facilities:** Sometimes the lack of facilities discourages some people from traveling: for example, some older and disabled people need seats and bus shelters to enable them to make local journeys (Titheridge et al., 2009) and concern about the lack of toilet facilities can cause anxiety for some people (Mackett, 2019).
- **Information:** Nowadays, much travel information is available on mobile phones. While 95% of all households in the United Kingdom owned a mobile phone in 2018, only 85% of those in the lowest income decile did so, and only 67% of retired people living alone mainly dependent on state pensions did so (Office of National Statistics, 2019).

The Role Transport Plays in the Relationship Between Social Exclusion and Health

Transport plays three main roles in the relationship between social exclusion and health: through providing access to facilities that offer health care and opportunities to follow a healthy lifestyle, through active travel that offers health enhancing physical activity, and through externalities that may have adverse effects on health that affect excluded people disproportionately.

Access

Travel offers access to various facilities that provide health benefits: to hospitals and other healthcare services to help reduce the risk of ill-health and to provide treatment when necessary, to facilities such as gyms that help promote well-being, to green spaces that offer physical activity, and to shops that sell healthy food. The difficulties discussed earlier that some socially excluded people have traveling mean that they are not able to enjoy the same health benefits as other people.

Access to healthcare without private transport is particularly difficult. The [Social Exclusion Unit \(2003\)](#) found that one third of people who did not own a car found it difficult to get to hospital compared to 17% of those who own a car. In 2017, 98% of car users in the United Kingdom could reach a doctors' practice within 15 minutes travel and 31% could reach a hospital, whereas the equivalent figures for those traveling by other modes were 72% for going to the doctors' and 5% for visiting a hospital ([Department for Transport, 2019b](#)).

Eating a healthy, balanced diet is an important part of maintaining good health ([NHS, 2019](#)). There is evidence that low-income areas with poor access to healthy foods are associated with higher cardiovascular risk factors ([Morris et al., 2019](#)). [Corfe \(2018\)](#) has examined the barriers to eating healthily in the United Kingdom. The report suggests that 10.2 million individuals in Great Britain live in areas where individuals without a car or with disabilities that hinder mobility may find it difficult to access a wide range of healthy, affordable food products easily. There are places where it is difficult to buy healthy food, but there are many fast food outlets selling cheap, unhealthy food ([Bowyer et al., 2009](#)). In some parts of Britain, this is because large supermarkets have been located on the edge of urban areas ([Furey et al., 2001](#)).

[Braubach et al. \(2017\)](#) show that green spaces can contribute to health and well-being, and discuss the available evidence about the beneficial effects they offer such as improved mental health through stress alleviation, reduced risks of cardiovascular disease, obesity, diabetes and death, and improved pregnancy outcomes by supporting physical activity and reducing exposure to pollutants, noise and excessive heat. However, many green spaces require a car to access them, so people who do not have access to one, including many socially excluded people, may not enjoy these benefits.

Travel as a Form of Physical Activity

The [World Health Organization \(2018\)](#) says that physical activity has significant health benefits and so walking and cycling can contribute to being healthy. The National Travel Survey ([Department for Transport, 2019a](#)) shows that, while the average distanced walked each year decreases with income, probably because of higher car availability at higher income levels, the average distance cycled in a year increases with income. Those in the highest income quintile undertake more active travel (walking and cycling combined) than those in the lowest quintile. This implies that people with low incomes, who are more likely to be socially excluded, receive fewer health benefits from active travel than others.

The Externalities of Transport

As discussed earlier, transport provides benefits by enabling people to reach opportunities including those that provide health benefits. However, transport produces externalities, that is, effects on people other than those using it. These include vehicular emissions that cause atmospheric pollution, noise, and injuries and deaths from vehicle collisions.

The adverse impacts of cars are concentrated in places where cars are driven, which are not necessarily the places where the users live. Vehicle emissions have an adverse impact upon health ([Buckeridge et al., 2002](#); [Zhang and Batterman, 2013](#)). The highest emissions of pollutants from cars tend to be in deprived areas ([King and Steadman, 2000](#)).

[Halonen et al. \(2015\)](#) found that long-term exposure to road traffic noise in London was associated with small increased risks of mortality, particularly for stroke in the elderly even after correction for the effects of traffic pollution. Groups with lower socioeconomic position have been found to be subject to higher environmental noise exposure, in general ([Dreger et al., 2019](#)).

[Edwards et al. \(2006\)](#) have shown that there is a relationship between deprivation and road traffic injury risk in London. The strongest relationship found was for pedestrians, where the most deprived were over twice as likely to be injured as the least deprived.

The higher levels of traffic along roads in areas where socially excluded people tend to live can lead to community severance by limiting social interaction with friends and neighbors. This can cause lower levels of well-being ([Boniface et al., 2015](#)).

Summing Up

This article has demonstrated the link between social exclusion and health and ways in which transport can affect the relationship. Whilst there are many other links between social exclusion and health, for example, in the political, social and cultural realms, it is clear that transport plays a role. It can also play a part in addressing social exclusion. [Mackett and Thoreau \(2015\)](#) outline some examples of transport interventions that might help reduce social exclusion and improve health, for example, by helping people find employment and so increase their income. One example where a transport policy was introduced explicitly to help address social exclusion and maintain well-being was the introduction of free off-peak bus travel for older and disabled people in Great Britain in 2008, which appears to have been effective ([Mackett, 2014a](#)).

Improving health and reducing social exclusion are important policy objectives, and there are useful synergies between them, with transport being a useful factor to facilitate some of the links, implying that suitable investment in transport may help to achieve both objectives.

Biography

Roger Mackett BA, MSc, PhD, FCILT, FCIHT is Emeritus Professor of Transport Studies at University College London. He has researched into various aspects of transport policy including the barriers to access for older and disabled people, the use of the car for short trips and the effects of car use on children's lives. He is a member of the Disabled Persons' Transport Advisory Committee (DPTAC) and the Standing Committee on Accessible Transportation and Mobility of the US Transportation Research Board (TRB).

Introduction

The Burden of Disease (BoD) is a tool to integrate health metrics and evidence into public health and nonhealth sectors (such as transport). BoD helps to integrate morbidity and mortality in the same unit, estimating base on the life expectancy, and the natural history of the disease, those years that certain populations will live with a disability-related to specific health diagnosis and those years of life lost due to premature death. BoD is a tool that can help health professionals and stakeholders understand the impact of different diseases and causes of death in a particular population. BoD can also help to compare different risk factors and how different health and nonhealth interventions can impact public health. The BoD is a framework for integrating, analyzing, and communicate, information that is available on a population's health, along with some understanding of how that population's health is changing so that the information is more relevant for health policy and planning purposes (Lopez et al., 2006). Transport policies have been related to several health risk factors (e.g., air pollution traffic incidents, physical activity, etc.). BoD will help to measure the health impacts of transport policies, based on risk factors, providing a standard health metric to compare transport policies and interventions with a health perspective (Fig. 1).

Burden of Disease Approach

The BoD is a concept developed in the 1990s by the World Bank and the World Health Organization (WHO) to describe death and loss of health due to diseases, injuries, and risk factors for all regions of the world (Lopez et al., 2006). The burden of a particular disease is estimated by adding together the number of years of life a person loses as a consequence of dying early because of the disease based on their life expectancy [called Years of Life Lost (YLL)]; and the number of years of life a person lives with disability caused by the disease, based on the natural history of the disease and life expectancy [called Years of Life lived with Disability (YLD)]. Adding the YLL and YLD provides an estimate of disease burden, called the Disability-Adjusted Life Year (DALY). One DALY represents the loss of one year of life lived in full health and is the primary health unit used by the BoD approach. Besides the DALY, several other measures have been devised, including the Quality-Adjusted Life Year (QALY), the health-adjusted life expectancies (HALE), and the Healthy Life Year (HeaLY).

The DALY is the most common measure used by the BoD approach and combines in one measure the time lived with disability and the time lost due to premature mortality. The following formulas describe how DALYs can be estimated:

$$\text{DALY} = \text{YLL} + \text{YLD}$$

where, YLL = years of life lost due to premature mortality. YLD = years lived with disability

The YLL corresponds to the number of deaths multiplied by the standard life expectancy (from the geographical location) at the age at which death occurs. The basic formula for calculating the YLL for a given cause, age, or sex, is:

$$\text{YLL} = N \times L$$

where, N = number of deaths. L = standard life expectancy at the age of death (in years).

To estimate YLD, the number of disability or disease cases is multiplied by the average duration of the disease and a weight factor that reflects the severity of the disease on a scale from 0 (perfect health) to 1 (dead). The formula for YLD is:

$$\text{YLD} = I \times \text{DW} \times L$$

where, YLD = years lived with disability. I = number of incident cases. DW = disability weight. L = average duration of disability (years)

Figure 1 Burden of disease in the context of transport policies.

Data Required for Estimate Burden of Disease

Number of deaths: the total number of deaths are the reported and registered number of fatalities on the specific cause of death, in a specific population in each time. This value can be found in the death certificate, health, and population statistics of the region and country. The number of deaths can be reported in an aggregation of estimates of deaths by cause, age, and sex by geographical location. For the estimating of YLL, a specific number of deaths for the geographical location under study should be chosen.

Standard life expectancy: life expectancy refers to the number of years a person can expect to live. By definition, life expectancy is based on an estimate of the average age that members of a population group will be when they die. The life expectancy can be obtained from national and regional vital registrations, census, and surveys. Global life expectancy at birth in 2016 was 72.0 years (74.2 y for females and 69.8 y for males), ranging from 61.2 years in the African Region to 77.5 years in the European Region. Women live longer than men all around the world. The gap in life expectancy between the sexes was 4.4 years in 2016. There are two main options when choosing the life expectancy in the BoD approach, (1) can use the latest available life expectancy of the country or region where the BoD is estimated, and (2) also can be used the highest life expectancy reported around the world, for example, Japan has a life expectancy of 85.3 years in 2017. The main decision between choosing one option is based on the assessor judgment based on a representative approach versus an equity approach. The representative approach (option 1) will choose the life expectancy of the county or regions where a BoD is performed; an equity approach (option 2) will assume that all the humans have the same potential to survive as the maximum reported in the best-case scenario, in other words, if Japanese people have a life expectancy of 85.3 years any human been can have the same life expectancy under a proper healthy life style.

Number of incident cases: incidence is the number of newly diagnosed cases of a disease in a specific population and time. The BoD estimations should use similar time frames for the number of deaths and incident cases in the population to estimate DALYs. Incident cases can be found in the official records and health statistics of a region or county.

Disability weight: A disability weight is a weight factor that reflects the severity of the disease on a scale from 0 (perfect health) to 1 (equivalent to death). Disability weights, which represent the magnitude of health loss associated with specific health outcomes, are used to calculate years lived with disability (YLD) for these outcomes in a given population. For example, a disability weight for mild diarrhea could 0.074 compare to severe diarrhea 0.24. But more severe health outcomes could have more impact on disability such as treated spinal cord lesion at the neck with a disability weight of 0.58 or an untreated spinal cord lesion at the neck with a disability

weight of 0.0.73. The most recent list of disability weight is provided by the global burden of disease (GBD) study in 2013 (Salomon et al., 2015).

Average duration of disability: The average duration of disability is the disease duration until remission, cure, or death. This is also called the natural history of the disease, where the process of the disease that without management or treatment could result in disease remission or death, and with management or treatment would result in the disease cure or control. The disease duration is based on the disease-incidence approach and can be found on scientific publications for the specific diagnosis. Traditionally, the BoD has been estimated by an incidence-based method. However, since the first GBD study in 2010, the prevalence-based approach has become more widespread. The prevalence-based approach estimates all health-related losses over the course of a year, whereas the incidence-based approach captures the burden of disease in new diagnostic cases. Since the incidence-based YLD is calculated as the sum of future health loss related to disease incidence in the reference year, it will not reflect the prevalence of all YLDs, nor does it accurately capture the time between which a disease occurs and the age at which health loss begins.

Other Health Indicators

Quality-adjusted life years is a statistical health indicator that reflects health quantity and quality. It was developed in the late 1960s by economists and is mainly used for cost-effectiveness analyses of improvements in social welfare and clinical interventions. The QALY method can estimate the number of years lived and the quality of life during those years that can be attributed to an intervention. When combined with the cost of providing intervention, QALYs are used to develop cost-utility ratios required to generate a year of “perfect health,” a perception of life without pain or disease. The health-related quality of life (or utility values) in QALYs are not linked to specific diseases but rather are based on individuals’ opinions about their own health state (patient weights) or on the judgments of others (e.g., a representative sample of the population, study researchers, or health professionals) about a particular health state (community weights where perfect health value = 1 and death = 0). The community weights integrate biomedical and psychosocial aspects of the BoD and consider five quality of life dimensions: (1) mobility, (2) pain or discomfort, (3) self-care, (4) anxiety-depression, and (5) usual activities (Lajoie, 2015).

Healthy life year combines the healthy life lost due to death with that lost due to morbidity. The healthy life lost requires knowing the incidence rate, case fatality ratio, the age of disease onset, the age of death, and the life expectancy at these ages. The HeaLY includes three components for disability: case disability ratio (CDR, analogous to the case fatality ratio), the extent of disability, and duration of the disability. The CDR and duration of disability can be determined objectively, but the assessment of the extent of disability, which ranges from 0 (no disability) to 1 (equivalent to death), may have a substantial subjective element (Hyder et al., 2012). An essential difference between the HeaLY and DALY is that the starting point for the HeaLY is the onset of disease; the loss of healthy life is based on the natural history of the disease (as modified by interventions). The YLD component of the DALY is similar, but the YLL is based on mortality in the current year. In a steady-state, there is no difference, but when there is a changing incidence, the DALY approach can significantly underestimate the health impacts.

Health-adjusted life expectancy is a health measure that summarizes the expected number of years to be lived in what might be termed the equivalent of full health. HALE provides one of the best summary measures for the overall level of health. Health expectancy indices combine the mortality experience of a population with the disability experience. In some cases, the HALE is calculated using the prevalence of disability at each age in order to divide the years of life expected at each age according to a life table cohort into years with and without a disability. Mortality is captured by using a life table method, while the disability component is expressed by additions of the prevalence of various disabilities within the life table. This indicator allows an assessment of the proportion of life spent in disabled states. HALE does not relate to specific diseases but rather to the average extent of disability among that proportion in each age group that is disabled (Hyder et al., 2012).

These BoD units are especially useful for policy comparison that affects different causes of mortality and different disease diagnoses. The BoD gives the stakeholders a unit of comparison that summarizes mortality and morbidity, comparing different diagnosis, helping to understand more comprehensively the magnitude and direction of a specific intervention, plan, program, or policy. The main disadvantage of these measures (DALYs, YLL, and YLD) is the difficulty to be interpreted for nonhealth practitioners, who are, in most cases, the final audience of a public health intervention.

Comparative Risk Assessment Approach

The comparative risk assessment (CRA) approach compares the changes of an intervention, policy, program, or plan on health determinants and their impact on the BoD (mortality and /or morbidity) compared with a baseline scenario or business as usual (Fig. 2). The aim of the CRA approach is to provide quantitative estimates of the expected health impacts (e.g., changes in premature deaths, cases of the disease, DALYs, etc.) and the distribution thereof among the population.

The steps of a CRA are:

- *Hazard identification:* The intervention, policy, or program context and the relevant exposure (or a multitude of exposures) needs to be identified (e.g., type of pollutant), and the baseline exposure level distribution of the population under study needs to be quantified.

Figure 2 Comparative risk assessment framework applied to air pollution.

- *Exposure assessment:* The exposure level at baseline is compared with the aimed at the exposure level of the counterfactual scenario, and the resulting difference in exposure level is quantified.
- *Exposure-response assessment:* An exposure-response function (ERF) that quantifies the strength of association between the exposure and the health outcome needs to be available from the literature or available guidance. The ERF needs to be of the best available evidence. In an ideal case, the ERF was estimated particularly for the population under study, reflecting most accurately the level of risk the population is exposed to. However, in many cases, an ERF for the population under study is not available; therefore, the ERF should preferably be a pooled, generalized estimate of the overall effect coming from a meta-analysis (or large longitudinal study).
- *Risk characterization:* The risk estimate obtained from the ERF that most epidemiological studies report in terms of relative risk (RR), which is the ratio of incidence observed at two different exposure levels, quantifies the strength of association between the exposure and health outcome. The risk estimate is scaled to the difference in exposure level resulting from the comparison of the baseline exposure level with the counterfactual exposure level.

In addition to these steps, when a policy plan or program is assessed is essential to consider the following points:

- *Scenario(s) definition:* A counterfactual scenario (or a set of scenarios) is defined, which describes the possible exposure level that is aimed at with the proposed intervention, policy, or program. Various criteria may determine the choice of counterfactual exposure distribution. Ideally, counterfactuals should represent intervention, policy, or program actions that are realistic and can be implemented (e.g., motorized traffic reductions to reduce air pollution levels in cities) rather than counterfactuals that are not achievable (e.g., zero air pollution). [Murray and Lopez \(1999\)](#) looked into different counterfactual scenarios categories and identified exposure distributions corresponding to theoretical minimum risk (i.e., exposure distribution with lowest population risk), plausible minimum risk (i.e., imaginable exposure distribution), possible minimum risk (i.e., exposure distribution observed in some populations), and cost-effective minimum risk (i.e., considers costs of exposure reduction).
- *Health outcome definition:* The health outcome (or multiple health outcomes) of interest needs to be defined that was shown by previous epidemiological studies to be associated with the exposure. A causal relationship between the exposure and the health outcome of interest is a prerequisite.
- *Health data identification:* The total burden (TB) of the health outcome of interest needs to be available for the population under study. Incidence rates are preferred over prevalence proportions because only new cases expected over a given time (i.e., incident cases) are preventable under the assumption that exposure levels will change.

Figure 3 Environmental burden of childhood disease in Europe 28 in disability-adjusted life years (DALYs). Source: Modified from Rojas-Rueda et al. (2019).

Examples of BoD and CRA

The GBD project is the most extensive, and most know example of BoD. The GBD is published each year and include a global perspective on multiple causes of the and diagnoses, providing YLL and prevalence YLD (Vos et al., 2015). The GBD provides multiple resources to communicate their results and DALYs, YLL, YLD can be consulted by country or region in their website <https://vizhub.healthdata.org/gbd-compare/>. The GBD provides different results based on age, sex, year health outcome, and risk factor, offering a great resource to consult the BoD of a specific geographical location, point in time, and health outcome a comparison among years, locations, age, sex, and outcome. The WHO also provides a GBD, and their estimates are produced on average every 5 years (WHO, 2019). The GBD from the WHO also provides DALYs, YLL, and prevalence YLD, globally, by region, country. More specific BoD focus on the environment is also available; recent studies have estimated the environmental BoD (EBoD) in specific age groups and geographical locations, such as in Europe (Rojas-Rueda et al., 2019). This EBoD focuses on estimating the health burden (DALYs, YLL, and YLD), related to specific environmental risk factors (e.g., air pollution, lead, secondhand smoke) and specific health outcomes (e.g., asthma). In this case, the EBoD instead of comparing health outcomes, compares the health burden of different risk factors (Fig. 3), with the aim to highlight the risk factors that could require more urgent policy interventions to improve public health.

In comparison to BoD, the comparative risk assessment approach does not focus only on quantifying health outcomes and risk factors. The CRA adds the dimension of an intervention to these assessments, comparing different policy scenarios and their impact on health determinants (risk factors) and outcomes. For example, Mueller et al. (2017a, 2017b) attributed almost 660 premature deaths and almost 10,000 DALYs to breaching WHO (PM_{2.5}) air quality guidelines in Barcelona, Spain, recognizing that motorized traffic is the most important contributor to local air pollution levels. In another study, Khreis et al. (2019) looked into the air pollution childhood asthma burden in 18 European countries with over 64 million children and estimated that if minimum pollution levels recorded for NO₂, PM_{2.5}, and BC could be complied with, then over 135,000, 190,000, and 89,000 incident cases of asthma could be prevented, respectively. A recent study assessed the Barcelona Superblock Model, an innovative land use intervention with the aims to reclaim space for people, reduce motorized transport, promote active transport, increase urban greening, and mitigate effects of climate change, found that with full implementation of the model, current city-wide annual mean NO₂ concentrations of 47.2 µg/m³ could be reduced to 35.7 µg/m³, which in return would result in 291 preventable deaths and an increase of average life expectancy by 129 days (Mueller et al., 2019).

Conclusions

The BoD approach and the CRA are essential and valuable tools to measure multiple health outcomes, risk factors, and transport policy interventions. Public health practitioners and authorities guide their policies base on several health metrics, and currently,

DALY, YLL, and YLD are the most common health metric used to assess the population health and compare health and nonhealth sector policies. Examples like the GBD, the WHO BoD and a single project on EBoD or CRA should be considered as good examples of how transport policies should be evaluated and assessed on health.

Introduction

The world is experiencing rising CO₂ and other greenhouse-gas emissions, resulting in climate change. The Intergovernmental Panel on Climate Change (IPCC) has warned that continuing increases in GHGs could trigger up to 6°C of warming over the next 100 years, while cutting CO₂ dramatically can still limit temperature change to 2°C or less (IPCC, 2013, 2019).

The IPCC (2019) report shows that reaching global carbon neutrality (zero net emissions on the planet) by 2050–60 is consistent with a 1.5°C climate target. All sectors will need to reach close to zero to achieve this. This paper considers the challenge of reaching a near-zero CO₂ emissions target for transportation worldwide by 2050. It reviews recent evidence and considers the technology/fuels-oriented barriers and strategies for hitting this target, though does not delve deeply into policy. It also does not consider major changes in travel patterns that could contribute to CO₂ reductions. The focus is on the technologies and fuels available to achieve this, and their potential for hitting final and interim targets along the way.

Transportation is one of the fastest growing sectors, with among the fastest rates of increase in CO₂ emissions, globally, in recent years, reaching 8.3 Gt or 24% of total energy-related CO₂ emissions in 2018 (IEA, 2020). It is rising due to rising activity across all transportation modes (at least before the 2020 pandemic hit). This rising activity has been offset to some degree by improved efficiency of vehicles, but not nearly enough to offset this activity growth. Within transportation, passenger road travel (cars, two wheelers, and buses) emitted about 43% (3.6 Gt), while trucks emitted 29% (2.4 Gt). Aviation and shipping each emitted around 10% (a little less than 1 t) (IEA, 2019).

CO₂ emissions from these major transport modes are mostly related to combustion of fossil fuels (typically gasoline, diesel, fuel oil, and jet fuel). Use of these fuels must be cut dramatically and eventually eliminated to achieve a near-zero CO₂ future. CO₂ must also be cut to near zero on a life-cycle basis, including vehicle and fuel production. The energy carriers electricity and hydrogen, produced from renewable sources (or fossil with carbon capture, or nuclear) are the primary approaches to achieving very low carbon energy systems for transportation.

Whether the world's transportation sector can reach a near-zero CO₂ target by 2050 will depend on many factors, especially technology potential, cost, and policies to move markets rapidly toward using these. In transportation perhaps more than any other sector, personal behavior will play a major role; households around the world must be convinced to alter their travel patterns and, especially, to adopt low carbon technology vehicles and fuels. Businesses will as well, and they are more likely to make choices on a cost-minimizing basis than households, so they may be even more difficult to convince, if costs are high. On the fuels side, industry, and power sector players must be convinced (or required) to reduce the carbon intensity of the energy they provide, including electricity, hydrogen, biofuels, and “electrofuels,” (fuels derived from electricity) among others.

While this paper focuses on advanced, very low carbon vehicle technology and fuel options, it should be noted that two other strategies can provide important CO₂ reductions over the next 10–20 years: conventional vehicle fuel economy improvements and changes in travel patterns. In each case, perhaps up to a 50% improvement in energy intensity could be achieved with very strong actions (such as substituting smaller, highly efficient vehicles for larger, less efficient ones, and for travel, a large-scale substitution of mass modes such as trains and buses for individual modes such as cars), going much beyond 50% would likely be very challenging, without changing to very low carbon technologies and fuels.

What Vehicle/Fuel Technology Options are There for Achieving the Targets?

From a vehicle point of view, electric and fuel cell vehicles are the obvious technologies for using decarbonized electricity and hydrogen, and must be priorities for changing road and rail transportation systems. For shipping and especially air, it may be difficult to use these energy carriers, given the need for long distance travel and thus for very energy dense fuels. In such cases, advanced, low-

Table 1 Overview of zero-carbon fuel options and issues

	<i>Electric vehicles and electricity</i>	<i>Fuel cells and hydrogen</i>	<i>Biofuels</i>	<i>Synthetic hydrocarbons ("electrofuels")</i>
Key current trends	Global average EV sales were around 2.5% in 2019 and growing, with about 20 million in service worldwide	Hydrogen is not yet significantly used as a transportation fuel. Around 10–15,000 commercial fuel cell vehicles have been sold (mostly in California) using H ₂	Up to 10% blends of ethanol or bio-diesel/renewable diesel are used in some countries, but there virtually no advanced (cellulosic based) biofuels production	Currently no known synthetic hydrocarbon commercial sales for transportation fuel anywhere in the world
Key infrastructure issues	Vehicle home and public charging infrastructure developing; few fast charging systems in most areas but their need is uncertain	Relatively little hydrogen storage/refueling infrastructure; led by 40 stations in California	Can be compatible with current ICE vehicles and infrastructure. Limits on ethanol and biodiesel but drop-in gasoline/diesel replacement fuels can go to 100%	Can produce drop-in replacement fuels, 100% compatible with current ICE vehicles and infrastructure
Critical path issues	Battery cost reduction; charger installation to support rapid sales	H ₂ electrolysis cost reduction and infrastructure scaleup to help reduce costs	Advanced technology cost reduction and scaleup	Electrolysis, Fischer–Tropsch and other technology scale-up to help reduce costs
Timing issues	Advancing rapidly, potential for 20%–50% shares in many countries by 2030	Early deployment phase; potential for 5%–20% sales shares in most markets by 2030	Current ethanol and biodiesel fuels widely available; large scale production of advanced fuels unlikely by 2030	Large scale production unlikely by 2030
Benefits	Low energy, running cost, zero emissions	Operation in FCEVs, rapid fueling, and longer range than BEVs	Compatible with ICE vehicles, possible low WTW GHG emissions	Compatible with ICE vehicles, potential very low WTW GHG emissions
Costs	High vehicle costs but dropping. Driving cost tends to be low given high efficiency of battery electric vehicles	FCEV purchase costs up to 50% higher than gasoline vehicles. H ₂ driving cost up to 3× that for gasoline, but may drop significantly by 2030 if scale is increased	Conventional biofuels are within 20% of the cost of petroleum fuels; advanced biofuels up to 2× cost	Very high costs of production (\$10–30/gge) likely until high volumes, mature market achieved

Source: Compiled by author based on a range of technical reports including *Fulton et al. (2019)*, *Brynnolf et al. (2018)*, *IEA ETP (2020)*, and *Witcover and Williams (2020)*, among others.

carbon biofuels and “electro fuels” (liquid fuels derived from electricity via production of synthesis gases) are the most obvious pathways.

Table 1 summarizes many of the advantages, disadvantages, and costs of different fuel and energy carrier options. A brief introduction to each technology category (table columns) follows:

- **Vehicle electrification:** Battery electric and plug-in hybrid vehicles can help unlock the route to zero emissions driving, as electric grids are decarbonized. EVs typically run on grid electricity with carbon intensity determined by the local electricity generation mix, but the world’s grids must be mostly decarbonized by 2050 to achieve the carbon neutrality targets in any case.
- **Fuel cells and hydrogen.** Fuel cell vehicles, running on hydrogen, offer the possibility of fast refueling and longer driving range than battery electrics. Hydrogen derived from grid electricity via electrolysis will decarbonize as the grid does. In some cases, hydrogen production could be off grid, such as from wind or solar parks connected to hydrogen electrolysis plants.
- **Biofuels:** There are a wide range of bio-based fuels, including those derived from waste bio-streams, renewable natural gas, and purpose-grown crops. Electricity and hydrogen can be derived from biomass, though here we mainly focus on liquid biofuels that are compatible with internal combustion engine (ICE) vehicles. The net GHG effects of any bio pathway are highly variant, mainly determined by feedstock and fuel production emissions (both direct and indirect effects.) Advanced options tend to derive from cellulosic feedstocks with very low process CO₂ emissions, leading to net-neutral CO₂ emissions.
- **Synthetic hydrocarbons:** These are typically high quality “drop-in” gasoline, diesel, or jet airplane replacement fuels, that can be fully blended (up to 100%, eliminating fossil components) and used by today’s vehicles. They can be produced from direct air (or process CO₂) capture and thermochemical processing to produce methane or long-chain hydrocarbons. These fuels contain CO₂ that will be emitted upon combustion, but since the fuel is produced via carbon capture, they can achieve net zero CO₂ emissions.

A common theme is that all (except electricity) are expensive at this time, and will require large scales and learning to bring costs down to reasonable levels. Other barriers will also need to be overcome, such as provision of refueling infrastructure (especially for hydrogen). Biofuels and synthetic hydrocarbons have the advantage of being compatible with today’s ICE vehicles.

It is notable that most of the liquid fuels described are compatible in high blend shares with today’s gasoline and diesel vehicles, giving them an enormous advantage in terms of minimum required vehicle and refueling infrastructure changes and investment requirements. These include drop-in biofuels and synthetic gasoline, diesel, and jet fuel from electricity (electrofuels), likely using

Figure 1 Recent and projected costs of various electrofuels, low/medium/and high cases (\$/gasoline-equivalent gallon). Source: Brynolf et al. (2018).

direct air capture. However, these fuels can be very expensive, and in the case of biofuels, the true life-cycle GHG emissions and some other sustainability factors are of great concern.

Scaling is also a major issue for these types of fuels, either in terms of sustainability (biofuels at high scale may be less sustainable than at low scale), or cost (both advanced cellulosic biofuels and most electrofuels may need very large-scale production to cut costs).

In fact, some of these fuels are already cost competitive, notably some conventional biofuels. For example, in the United States in 2019, the retail costs of traditional biodiesel and ethanol were competitive with diesel and gasoline respectively, though that reflects some differences in tax levels between them and petroleum gasoline and diesel (Clean Cities, 2020). Renewable diesel, made mainly from hydrotreated vegetable oils, and a drop-in fuel (up to 100% blends), is somewhat more expensive but still sells within 30% of the price of diesel fuel.

However, the production cost of advanced biofuels, such as ethanol or drop-in gasoline and diesel replacement fuels from cellulosic feedstocks, is much higher and very little is produced today. These costs may be up to twice the production costs of gasoline and diesel, though should get much close to those costs as plant sizes, capacities, and volumes rise, at least as suggested by modeling studies (Witcover and Williams, 2020).

But what about the other advanced fuel types with the potential for net-zero CO₂ operation? Fig. 1 summarizes the findings of a recent paper (Brynolf et al., 2018) containing a meta-analysis of 24 studies that provided detailed cost estimates for future, large-scale production of various types of electrofuels.

Clearly, there is potential for an eventual large scale electrofuels future where these fuels can be produced at something close to competitive with gasoline and diesel fuel, especially if those fossil fuel costs rise with rising oil price. But near term, low volume production costs are estimated to be very high, on the order of \$6–14 per gasoline-equivalent gallon. Such costs may be “non-starters” for most investors. Only governments could support a process of building capacity and achieving enough volume and experience to bring down these costs to eventually have a chance to be competitive without subsidies.

It is important to note that the table and figure do not account for vehicle efficiency using those fuels; in all liquid fuel cases, the efficiency of ICEs would be similar to those using gasoline or diesel; however for hydrogen, fuel cell vehicles could provide a 30%–50% efficiency benefit, making this option potential much cheaper from a fuel cost standpoint; however, this option also required a complete changeover to fuel cell vehicles, and investment in hydrogen system infrastructure (storage, fuel distribution, and refueling stations) to support this. With retail hydrogen at \$6/kg (about \$6/gallon gasoline-equiv), fuel cells would be able to operate at close to the driving cost of gasoline vehicles. And this type of cost may be the easiest to achieve of all the electrofuels. Thus, hydrogen and fuel cells are often considered to be among the most promising of these options.

National/Regional Progress to Date and Targets

So where do countries actually stand on some of these in terms of progress and plans? As shown in Table 2, as of late 2019 there has been little commercial scale progress in any area except electric vehicles. EV sales shares have been rising though the 2020 pandemic

Table 2 EV status and targets as of 2019 for key countries and regions

	<i>California</i>	<i>USA</i>	<i>EU</i>	<i>France</i>	<i>Norway</i>	<i>Japan</i>	<i>China</i>	<i>World</i>
2019 New light-duty electric vehicle (EV) sales share	8%	2%	3%	4%	56%	2%	5%	2.6%
Target EV sales shares or ICE ban year	15% by 2025, 100% by 2035	None	None	ICE ban by 2040	ICE ban by 2025	None	None	NA

Source: IEA GEVO (2020), various news reports of EV sales targets and ICE ban dates; CA governor's executive order, October 2020.

may slow the rates in some countries. Some countries (and the US state of California) have also set ambitious targets for future sales, or set a ban on ICE vehicle sales in the future.

The EV shares in these countries have grown fairly rapidly, though the question is whether this rate of increase will continue into the future. California notably recently set truck ZEV sales requirements to 2035, reaching 100% ZEVs (zero-emission vehicles) for cars and as high as 75% ZEVs in the sales mix for medium duty (delivery type) trucks. These can be battery electric, plug-in hybrid or fuel cell vehicles. Many other countries have set "soft" targets for such a phase out in the 2035–40 time frames, with Norway leading the way with a 2025 phaseout plan.

Scenarios for Achieving CO₂ Reduction Targets

In 2019, the IEA created a "Sustainable Development Scenario" that is believed would be consistent with a 1.7–1.8°C warming increase (WEO 2019). It projects to 2040, and the scenario would cut total energy-related GHGs between 2020 and 2040 by about 40%, on a path toward net-zero emissions globally by around 2060–65. Extracts from **Tables 2 and 3** of that WEO show a reduction in transportation CO₂ of about 35% between 2025 (its peak year) and 2040.

How does the IEA suggest achieving such reductions? Basically by introducing low carbon technology vehicles and fuels, and ramping up sales of these as fast as is reasonably possible. In particular, electric vehicles play a major role for cars and trucks, and low carbon fuels play a major role for shipping and aviation. IEA's scenario includes key milestones for 2030 and 2040. These are shown in **Table 3**, along with this author's estimates of where they would need to be by 2050.

The IEA scenario sets their 2030 and 2040 targets based on ambitious policy and technology progress, and even these do not put the world on a path to achieving near zero transportation by 2050. As per this author's additional targets for 2050, very rapid changes will be needed between 2040 and 2050 to hit targets. But if the world has made the types of progress envisioned by the IEA by 2040, this "big push" to 2050 should be possible in all transportation modes. Also, the figures in the table show global averages; in 2030 and 2040, leading countries will need to do even better than the IEA global averages shown.

Overall, the IEA is showing that even to achieve a global transportation system emissions reduction of 30% between 2017 and 2040, consistent with a broader 1.7–1.8°C target, a veritable revolution will be needed. And this revolution will need to happen faster in wealthier countries, more able to invest in new technologies and systems, with other countries following along and adopting technologies as they become cheaper and available in large volumes. The lead countries and regions appear likely to be Japan, China, the EU, and the US—or at least California.

How Can We Achieve the "Revolution"?

A look again at **Table 3** provides some sense of how fast the world must move in particular areas. For example, electric PLDVs reach 236 million by 2030, out of around 1.5 billion expected vehicles on the planet in that year. But to reach that stock level, sales must

Table 3 IEA scenario targets to 2040, compared to needed 2050 targets

	<i>2030 (IEA)</i>	<i>2040 (IEA)</i>	<i>2050 (This author)</i>
Light duty electric vehicle stocks	236 million (around 20% of world total)	933 million (around 60% of world total)	Near 100% of around 2 billion vehicles on world's roads
Average carbon intensity of world's truck fleets	33% reduction in average CO ₂ intensity vs. 2020	60% reduction	90%–100% reduction
Total shipping emissions	Similar to 2020	20% reduction	80% reduction
Total aviation emissions	Similar to 2020	10% reduction	80% reduction

Notes: 2030 and 2040 changes from IEA WEO (2019), 2050 targets set by this author given overall goals.

grow very rapidly and may need to account for at least 30% worldwide in that year, or around 30–40 million. This in turn suggests that electric vehicle sales in leading countries may need to be 40%–50% in 2030.

Similarly, freight truck carbon intensity drops by a third, meaning carbon intensity of new trucks in leading countries probably should drop by at least half. This can be achieved through a combination of conventional truck fuel economy improvement, and the introduction of electric and hydrogen trucking, with rapid growth in sales.

Shipping and aviation can be thought of in global terms (as in the table), and move more slowly than land transport, but leading countries still need to push harder, buying efficient new planes and promoting low carbon fuels; at least a 30% reduction in carbon intensity in these modes (taking into account travel growth) will be needed.

To achieve targets like this, in the next 10–15 years there must be a relatively strong reliance on electric vehicles for light duty; electric and hydrogen vehicles for trucks; and liquid biofuels for ships and aviation. The most advanced liquids are not yet available and this may slow progress for these vehicles, but the hope is that these vehicles can catch up post-2030. An additional challenge will be bringing down the high cost of such fuels, along with hydrogen. The most likely way to do this is to force the technologies and fuels into the market (regulations and pricing policies), and create the scales needed to achieve much lower costs.

Eventually, by 2050, there is a reasonable prospect that very large volumes of electricity, hydrogen, and advanced zero (net) carbon liquids will be available at reasonable prices, and allow a near-zero CO₂ transportation system to be realized.

Concluding Remarks

This review suggests that:

1. Reaching very low CO₂ emissions by the 2050–60 timeframe will require very rapid changes in the sales of vehicle technologies by 2030 and 2040. The changes will be unprecedented and will require very strong policy efforts around the world to achieve.
2. Some technologies, notably vehicle electrification and electricity carbon reduction, have a “head start” over most other technology/fuel options, and may be among the least expensive overall for consumers, given their efficiency and the declining cost of batteries.
3. Hydrogen can become a reasonably low-cost energy source when used with fuel cell vehicles, since these vehicles are very efficient, making this a front-runner option; however, it does require a complete change in vehicle technology and refueling infrastructure and an associated policy commitment.
4. Today’s biofuels (ethanol from grains and biodiesel or renewable diesel from plant oil seeds) provide a competitive near-term option, but with limited CO₂ reduction benefits and significant sustainability concerns. Longer-term options, mostly derived from cellulosic feedstocks, can help address these concerns and provide “drop-in” fuels, but are likely to be expensive.
5. There are other technology/fuel options that could provide zero-emissions transportation, notably, “electrofuels”—producing gaseous or liquid fuels from electricity with carbon capture. The liquid fuels could generally be compatible with today’s gasoline and diesel vehicles, so have a major advantage in avoiding the need for a vehicle technology transition.
6. However, the advanced biofuel and electrofuel options are very expensive in the near term and would require enormous investments (perhaps tens or hundreds of billions of dollars) to achieve large-scale volumes with a chance to reach long-term, more competitive production costs. Returns during a transition period could be low or negative, raising questions about who would be willing to make these investments. Strong government interventions will likely be needed.

Overall a range of technologies and fuels (energy carriers) exist to achieve very low carbon transportation systems by 2050–60, if strong commitments to this transition were made. But the costs of transitions may be high and strong policy pressure must be applied to ensure a rapid, smooth transition. The current pandemic (as of time of writing) has slowed travel growth, but also may be slowing the uptake of new technologies. It is highly uncertain what near-term or long-term effects it will ultimately have, but it must not stand in the way of a rapid transition to very low carbon technologies if the targets are to have any chance of being met.

Introduction

Disability affects a substantial proportion of the world's population, and it is therefore important to understand issues affecting disabled travelers in order to ensure that the design and delivery of transport systems and services take these issues into account. The best estimates show that disabled people comprise approx. 15% of the world's population (WHO, 2019; United Nations, 2015). This proportion has been increasing, and current expectations are that these numbers will continue to rise over the coming decades. The upward trend in disability stems from the trend toward an ageing population, and the higher risk of disability amongst older age-groups, and the increasing prevalence of chronic health conditions, such as diabetes, cardiovascular disease, cancer, and mental health disorders. The proportion of the population affected is even more significant if we consider the extended concept of persons with reduced mobility (PRM). This includes not only disabled people, but also other people who face barriers to their mobility, including older people and people with temporary impairments (such as a broken limb). It is estimated that PRM comprise approximately a third of the population (isemoa.eu).

It is timely to reflect on the issues facing disabled travelers. First, it is now over two decades since countries began to enact legislation to promote greater inclusion of disabled people in society, and 15 years since the UN drew up the Convention on the Rights of Persons with Disabilities (UNCRPD). Secondly, we are currently in the midst of a technological shift affecting transport in potentially profound ways.

This article seeks to provide a concise review of the current state of knowledge in relation to disabled travelers. It will start with some context and then some statistics, before addressing the questions of why disabled people's travel patterns are different to those of nondisabled people, why this situation exists and why it matters. The article then turns to look at what can be done, to provide pointers to some examples of good practice and to consider the possible implications of technological and other future trends for disabled travelers. A set of further reading is then provided, for the interested reader to delve more deeply.

Some Context

How one defines "disability" is contested, but the social model of disability is arguably the more useful perspective for the purposes of public policy. The different ways of understanding and conceptualizing disability vary in relation to the extent to which it is viewed as a medical issue or a social issue; that is, whether the source of disability is viewed as emanating from the individual's medical condition or from society's failure to organize itself in a way that accommodates the diversity of the population (Oliver, 1983; and UPIAS, 1976). Viewing it from a social perspective has the effect of turning attention to how society can adapt and become more inclusive and accessible.

The social model of disability draws a distinction between a person's impairment and the disablement they experience. Impairments are defined as conditions or characteristics specific to individuals, such as deafness, blindness, autism, wheelchair-use etc. Disablement is defined as the oppression experienced by people with impairments. That is, impairment is something that belongs to the person, whereas disablement is something that is done to the person.

Having identified the distinction between disability and impairment, it is important to acknowledge the wide range of impairment types and, thereby, the diversity amongst disabled people, as this has a direct bearing on transport and travel. Impairment types are grouped differently by different organizations. One generic disaggregation is into physical, sensory, and cognitive impairments.

Table 1 Disability prevalence disaggregated by impairment for Great Britain (millions)

By way of example, **Table 1** shows the incidence of disability, disaggregated by impairment type for Great Britain. It can be seen that the total population of disabled people is some 11.6 m (approx. 20% of the total population), and yet the disaggregated numbers add up to more than this total. This is because many disabled people have more than one impairment.

To take just one comparative example as a means of illustrating the importance of understanding the role of impairment type, the experiences of a disabled traveler who is a wheelchair user will be different in a number of ways to the experiences of a disabled traveler who has a visual impairment. For instance, if a wheelchair user embarks on a journey and discovers that completing that journey necessitates the use of a flight of steps, they will either be unable to complete that journey or have to divert their journey in order to take a route that allows them to avoid those steps. In contrast, so long as the visually impaired person is aware of those steps, then their journey will not usually be disrupted. On the other hand, a visually impaired person waiting at a bus stop may find it extremely difficult to know when the specific bus service they need has arrived at the stop, whilst a wheelchair user would typically have no difficulty with this. Some aspects of being a disabled traveler will, however, be common across different impairment types, such as the potential for experiencing negative attitudes from other travelers or from transport staff.

Disabled Traveler Statistics

On average, disabled people travel substantially less than nondisabled people, and this is not simply a reflection of their preferences. Evidence shows that disabled people travel a third less than is the average for nondisabled people (NTS, 2014) in terms of distance traveled. Furthermore, Clery et al. (2017) look at proportions of the population who make fewer than 400 trips a year. They find that over 26% of disabled people who have difficulty with one or more transport mode make fewer than 400 trips per year, whilst amongst nondisabled people this figure is 13%.

Research also demonstrates differences in transport use by disabled people with different types of impairment. For instance, Clery et al. (2017) find that 64% of people with self-care difficulties, 59% of people with balance difficulties and 52% of people with sight difficulties never use public transport; by comparison, 42% of nondisabled people never use public transport.

In part, differences in travel patterns between disabled and nondisabled people can be explained by other differences between disabled and nondisabled people, such as employment rates (unemployment rates being much higher amongst disabled people than nondisabled people) and perhaps individual preferences. However, there is also evidence that disabled people would travel more if conditions were improved.

Why are Disabled Travelers' Travel Patterns Different to Those of Nondisabled People?

Disabled travelers face a range of difficulties when traveling that nondisabled travelers do not face, and this is probably the key reason why trip rates and travel patterns diverge. The difficulties faced by disabled people when making journeys are often referred to as "barriers", rendering parts of the transport system partially or entirely inaccessible. These barriers have been categorized into a number of groups:

1. Physical design (of the built environment and of transport infrastructure and vehicles);
2. Transport service availability/proximity;
3. Financial affordability;
4. Information and awareness; and
5. Training.

Thinking about physical barriers, a wheelchair user will find it difficult or impossible to use parts of the transport system that require the use of steps. Furthermore, if there is uncertainty about whether a particular journey made by a particular mode will or will not require the use of steps, this will serve to discourage a wheelchair user from making that journey by that particular mode. It is these sorts of considerations that suppress trip rates and constrained mode choice, and highlight the importance of the “trip chain” and of specific accessibility-related travel information.

The concept of the “trip chain” is important as, just as a chain is only as strong as its weakest link, a trip is only as accessible as its least accessible link. That is, any journey will be made up of a number of stages or links. These can include the walk from one’s front door to the nearest bus stop, accessing and waiting at that bus stop, purchasing a ticket and boarding the bus, locating a seat and so on. At any of these links, disabled people may experience difficulties due to one or other accessibility problem associated with that link. The concept of the trip chain highlights the potential for a significant accessibility problem at just one of these links to render the whole journey impossible.

In a transport system that comprises some parts that are accessible, some that are partially accessible and others that are entirely inaccessible, the role of specific accessibility-related information becomes vital. If a disabled traveler knows that each stage of the journey they wish to make is accessible for them, then this will give them greater confidence to make that journey. If, on the other hand, a disabled traveler knows that one or more stages of the journey they wish to make will be partially or entirely inaccessible for them, they will be able to plan accordingly—whether that be to seek assistance for those difficult stages of the journey, or to somehow make alternative arrangements.

Added to the groupings of barriers identified above, there is the specific issue of the safety of disabled travelers. It is observed that disabled travelers tend to self-regulate their behavior in order to avoid dangers (e.g., that might arise from their diminished reaction-times, increased physical frailty etc.) and mitigate accident risk. However, this tends to mean that they suppress their travel and mobility in some way, and so safety becomes closely linked with issues of access, inclusion, physical activity, wellbeing, and public health.

Why do These Difficulties Exist and Persist?

Thinking within the social model of disability, these difficulties stem from transport systems and services having been designed without regard to how disabled travelers would use them. The practice of “inclusive design” is a relatively recent one (Design Council, xxxx) and much of the transport system we have today dates back to an era when attitudes towards and awareness of disabled people were very different to those that exist today.

In more recent times, governments and international agencies have introduced legislation, regulations and guidelines in an effort to ensure that transport systems become more accessible for disabled travelers. The Americans with Disabilities Act (ADA), in 1990, was something of a landmark, creating a set of rights for disabled Americans and a set of obligations for service providers. Since then, many countries have implemented broadly similar legislation. At the international level, the United Nations has drawn up the Convention on the Rights of Persons with Disabilities (UNCRPD), which includes articles on accessibility and mobility, whilst the EU has introduced a comprehensive framework of passenger rights, explicitly encompassing disabled passengers.

In some instances, the legislation includes regulations and/or guidelines setting out how service providers should or must adapt services to ensure they are inclusive. For instance, in the UK, the Equality Act (2010) incorporates a set of Rail Vehicle Accessibility Regulations that set out the requirements of new rail vehicles. This approach of providing regulations has been praised for its clarity, but it has also been criticized for stifling innovation. In either case, there are calls for such regulations to be reviewed and updated periodically, to ensure that they continue to reflect the requirements of disabled travelers.

Whilst regulations can be monitored to ensure they are adhered to, rights must be enforced, and this can prove difficult. Some countries have introduced public enforcement bodies to assist with this, but even where these exist, enforcement is often down to private individuals bringing forward legal cases, which many are reluctant to do.

It is often argued that inclusive design costs relatively little if incorporated into project plans at the outset, and a variety of design guidance has emerged to enable inclusion to be designed in from the start. More recently, concern has focused on how disability access is taken into account as part of transport investment decision-making processes.

Why Does This Matter?

There are a number of ethical, legal, social, and economic arguments as to why travel for disabled people matters. From an ethical and legal perspective, it is argued that disabled people should have an equal right to travel and should not be subject to discrimination on the grounds of being disabled. These arguments have served to frame the legislation referred to above. Whilst they are quite commonly accepted, there remains some disagreement regarding how these rights fit alongside other sets of rights and about how to fund the cost implications arising from these rights. As a means of managing this disagreement, the concept of “reasonableness” has been introduced.

Social and economic arguments center on the diminished life opportunities disabled people face as a consequence of their travel being limited due to the constraining effects of inaccessible transport systems. That is, the suppression of disabled traveler’s mobility can lead to a range of social and economic problems, including heightened levels of loneliness, reduced levels of physical activity,

reduced levels of employment and reduced levels of economic, and cultural participation. Furthermore, these can then lead to consequent health problems, which also have both social and economic dimensions.

What Can be Done?

It is generally acknowledged that the key to tackling problems faced by disabled travelers is to address each of the key barriers to accessible travel, referred to above. This is likely to involve incorporating inclusive practices into the design of infrastructure and services, ranging from physical infrastructure, customer support, information provision and digital technologies. As a starting point, much will be achieved by complying with legislative regulations, as referred to above, and with industry guidelines (refs xx). Furthermore, there are a number of excellent compilations of good practice that have been compiled on behalf of the European Commission (MEDIATE, 2014; and xx, 2019).

Technology to Assist

The following broadly adopts the categorization set out in “New Transport Technology for Older People” (OECD, 2004), which remains a very relevant document. This makes a three-way division of technological applications, as to whether they are applied to a vehicle, a person or to the physical infrastructure.

“In-vehicle systems” for private cars have generally been developed by motor manufacturers based on commercial incentives to increase driver safety, confidence and comfort, with an awareness of the growing size of the older driver market. A range of systems exist including:

- Adaptive Speed Control;
- Night Vision Displays;
- Navigation Systems;
- Gap-Estimation Aids; and
- Workload Management Systems.

Personal technologies are being used to develop solutions for different groups of disabled travelers. A great deal of effort has focused on technologies to assist visually impaired people. To a lesser extent, solutions have also targeted wheelchair users and others with reduced mobility, and for people with hearing or other communications impairments. Key amongst these technologies is personal navigation aids—which can be disaggregated into two further subcategories:

1. Passenger guidance for visually impaired people seeks to make use of satellite navigation technologies, in conjunction with screen magnification and speech synthesis technologies, in order to provide route navigation and way finding information to people with a visual impairment. Passenger guidance based on GPS and mapping technologies, often referred to as Personal Positioning Systems (PPS), have been implemented via specialist and, more recently, more mainstream applications (apps) designed for internet-enabled mobile phones and smart phones, since the required technologies are often already integral to the mobile device. A number of such apps exist. Furthermore, the Royal National Institute of Blind People (RNIB) has been conducting ground-breaking work in the areas of Augmented Reality, Electronic recognition, and artificial vision. They see these as forming part of a “Blended technological” solution, whereby technologies serve to complement techniques already being used, such as the long white cane and the guide dog.
2. Tailored accessibility-related information and communication apps for wheelchair users and people with otherwise reduced mobility draw on digital maps and crowd-sourced data, often provided in real time.

New technologies have also been embedded into the physical infrastructure of the built environment. Triggered Information, via the use of Beacons, has been the subject of research and development, and the RNIB has recently launched its Update to their REACT system of talking beacons for visually impaired people. A further idea is that of “Electronic lead lines”, whereby RFID tags are fitted to the visually impaired person or to their long white cane, which then interact with tags in the environment. The aim is to enable the visually impaired person to be prompted and guided in unknown environments, but it could also serve to improve cognitive awareness of one’s surroundings. The Austrian “ways4all” project has undertaken ground-breaking work in this area, establishing several demonstration sites in Vienna. However, it is not possible to embed RFID tags everywhere, so the question returns to the issue of how to use what is already there to best effect.

Speculations About the Future

There are several scientifically exciting technological developments taking place, but a number of difficulties remain. Technology take-up, particularly amongst older age-groups and lower income groups seems to continue to be a problem. Likewise, technology abandonment has been shown to be commonplace, particularly where that technology has been designed especially for the elderly

and disabled market. This would seem to be a result of several factors including awareness of the technologies, cost to the individual, accessibility/user-friendliness of the technology itself, and a lack of availability of training specific to the technologies. Add to this the problem of battery life for the devices, and it would appear that new technologies might be best-seen as providing a complement—albeit a powerful one—to a travel environment that is itself inclusively designed.

Increasing levels of automation within the transport system is likely to have a number of advantages and disadvantages for disabled travelers. The issues encountered will differ by transport mode and by the specifics of the traveler's impairment.

On public transport, automation is likely to lead to a greater reliance on ticket machines and on online information and booking services, and reduced staffing in the system. These developments may make life easier for disabled travelers who have difficulties in accessing traditional ticket windows or with communicating via the spoken word. However, they may make life more difficult for those disabled travelers who require staff assistance with travel.

Increasing automation of private cars would be expected to make the driving task progressively less demanding. Ultimately, the driverless car (at level 5 of automation) might be expected to make private car-use universally accessible, even to those currently ineligible to drive such as blind and partially sighted people. However, ongoing consideration is needed to ensure that autonomous vehicles and that the infrastructure to support them is designed so as to be accessible. Furthermore, precaution is needed with regard to personal security issues and to what happens in the event of emergencies (such as the automation failing and the vehicle having to revert to manual drive).

Lastly, traveling in the wake of Covid-19 brings forward a range of new issues for disabled travelers. It is too early to say how travel will adapt in the coming years, but requirements for face-coverings and social distancing are two areas that pose difficulties. On the other hand, less crowded public transport and a greater potential to access opportunities remotely (without the need to travel), are likely to be of benefit to disabled travelers.

Introduction

The impacts of connected and automated vehicles (CAVs) on traffic flow, travel behavior, and infrastructure have been discussed in previous chapters (10110, 10110, 10636, and 10640). The focus of this chapter is on the health implications of CAVs, which has received relatively less research attention in recent years (Milakis et al., 2017). The discussion presented in this chapter links the previous chapters regarding the impacts of CAVs on transportation (10110, 10400, 10636, and 10640) and the discussion on the impacts of transportation on public health (10731, 10732, 10733, 10737, 10738, and 10742).

This chapter investigates three major questions surrounding CAVs and public health:

1. How do CAVs impact public health?
2. To what extent do CAVs impact public health?
3. What actions are needed before and after implementing CAVs?

To answer these questions, I collected and studied research on the health implications of automated vehicles (AVs), connected vehicles, and CAVs, with a special focus on recently published review studies (Crayton and Meier, 2017; Dean et al., 2019; Rojas-Rueda et al., 2020; Singleton et al., 2020; Sohrabi et al., 2020). The answers to these questions should benefit transportation engineers, urban planners, car manufacturers, the healthcare sector, and policymakers. It could help them understand the effects of CAV implementation on public health, allowing them to make more informed decisions regarding investments in CAVs and their deployment. It also is expected to urge stakeholders to intervene and mitigate negative health consequences and facilitate the positive impacts of CAV implementation.

CAVs Present Benefits and Risks to Public Health

There are two orders of impact when investigating CAVs health implications. First-order impacts refer to those resulting from changes in transportation—including the systems, infrastructure, land use, and activities behind it. Second-order impacts are consequences of the first-order impacts, as well as the policies and actions that govern the negative consequences of CAVs. In subsequent sections, the potential CAVs' first- and second-order health implications are discussed through 32 and 6 pathways, respectively (Fig. 1).

First-order Impacts

A study by Sohrabi et al. (2020) proposed a framework to identify the health impacts of AVs through the changes in transportation. To this end, first, the changes in transportation were investigated using seven points of impact, including transportation jobs; transportation equity; land use and the built environment; traffic flow; trip, mode and route choice; transportation infrastructure; and traffic safety. Then, 14 areas where transportation can affect public health were discussed—access, mobility independence, social exclusion, contamination, greenhouse gases, community severance, heat, noise, air pollution, stress, green spaces, physical inactivity, electromagnetic fields, and motor vehicle crashes. Ultimately, the AVs implementation was linked to public health through 32 pathways. Fig. 2 shows the proposed framework by Sohrabi et al. (2020). The pathways are labeled as having negative, positive, and uncertain impacts, given the direction of AVs' health implications through each pathway.

Figure 1 CAVs first- and second-order health implications.

Considering the communication capabilities of CAVs, along with its advantages and infrastructure requirements, the 32 pathways between CAVs and public health are identified. I have discussed the 32 pathways in the context of CAVs' seven points of impact on transportation:

1. *Transportation jobs*: The deployment of CAVs can eliminate driving jobs as well as vehicle service-related jobs (Groshen et al., 2019; Pettigrew et al., 2018). This loss of jobs can result in social exclusion, which has adverse health consequences (Holt-Lunstad et al., 2015).
2. *Transportation equity*: CAVs have the potential to provide mobility options for individuals with disabilities, the elderly, and nonlicensed drivers (Bennett et al., 2019a, 2019b). This would facilitate access to healthy food and healthcare, promoting public health by improving mobility independence and social inclusion (Holt-Lunstad et al., 2015).
3. *Land use and built environment*: Cheaper, more comfortable, and easier travel facilitated by CAVs would incentivize drivers to travel longer distances, ultimately resulting in urban sprawl (Milakis et al., 2017). As a result of urban sprawl, the total vehicle miles traveled (VMT) would increase (Childress et al., 2015), and accessibility would be reduced in urban areas (Milakis et al., 2017). On the other hand, there would be a reduction in parking needs (Zhang et al., 2015) and space would be freed in urban areas. The increases in VMT can be translated into increases in adverse public health impacts from traffic-related noise (WHO, 2018), heat (Cheng et al., 2014), greenhouse gases (GHG) (Haines et al., 2006), air pollution (Cesaroni et al., 2014; Kurt et al., 2016), and contamination (Jaishankar et al., 2014). Urban sprawl restricts accessibility and community interactions, resulting in health consequences from social exclusion (Holt-Lunstad et al., 2015). Potential changes in urban design can affect public health through accessibility to green spaces (Gascon et al., 2016) and active transportation (Kyu et al., 2016); however, the direction of these changes is unclear.
4. *Traffic flow*: Since CAVs can gather information by communicating with infrastructure and other vehicles, and sensing the environment, they drive more smoothly by optimizing the acceleration and deceleration (Milakis et al., 2017). Given that CAVs emit less harmful pollutants—including heat, GHGs, air pollutants, and contaminants—they have a low impact on human health. The implications CAVs have on health owing to noise are uncertain. On the one hand, traffic noise may be reduced by less acceleration and deceleration of CAVs. On the other hand, the expected increase in flow speed can increase overall noise emissions (WHO, 2018). While traffic-related stress is associated with adverse health impacts (Hackett and Steptoe, 2017; Kivimäki and Steptoe, 2018; Schnurr and Green, 2004), self-driving CAVs can eliminate the stress caused by driving and traffic congestion, promoting public health.
5. *Trip, mode, and route choice*: CAVs can improve the mobility of individuals with disabilities, those who are nonlicensed, and the elderly, resulting in increased travel demand (Milakis et al., 2017). In addition, more affordable travel options encourage a modal shift from public transit and active transportation to private cars (Milakis et al., 2017). As a result, an increase in VMT is expected after the implementation of CAVs. As discussed previously, the higher the VMT, the higher the levels of adverse health impacts owing to noise, heat, GHGs, air pollution, and contamination. Furthermore, the modal shift from active transportation to motorized vehicle transportation can reduce physical activity (Sohrabi et al., 2020) and negatively impact public health (Kyu et al., 2016). An increase in motorized traffic is associated with community severance (Mindell et al., 2017), which also has adverse health impacts (Cohen et al., 2014; Emond and Handy, 2012).
6. *Transportation infrastructure*: We expect a change in transportation infrastructure needs with the introduction of CAVs, depending on the potential changes in travel demand and transportation modal splits. Paved surfaces, such as roads and parking lots, are a source of heat in urban areas (Coseo and Larsen, 2014). Also, the growth in transportation networks contributes to community severance, as it occupies green spaces (Sohrabi et al., 2020). In addition to the negative health impact of transportation

1. Traffic accidents are a major source for organ donations; in 2019, 12% of all donations in the United States were from motor-vehicle crashes ([Organ Procurement and Transplantation Network, 2020](#)). Consequently, CAVs impacts on motor-vehicle crashes could result in changes in organ donation numbers ([Rojas-Rueda et al., 2020](#)). Given the uncertainties regarding CAVs impacts on traffic safety, the health implications of CAVs through changes in organ donation remain uncertain.

2. According to Singleton et al. (2020), CAVs can promote travel satisfaction, which (indirectly) affects life satisfaction (De Vos, 2019). Given that life satisfaction is associated with positive health impacts (Collins et al., 2009), CAVs have the potential to positively impact public health.
3. Shared CAVs can facilitate ridesharing, leading to substantial transportation and environmental benefits (Krueger et al., 2016). However, Rojas-Rueda et al. (2020) highlighted the potential negative health impacts of shared CAVs owing to the spreading of communicable diseases.
4. The partial and fully self-driving capabilities of CAVs allow passengers to use drugs and alcohol (Rojas-Rueda et al., 2020). At lower levels of automation, substance abuse can result in impaired driving and negative safety consequences.
5. The changes in transportation—particularly the need for new infrastructure—can result in changes in road constructions. Road construction creates particulate matter with diameters $<10\text{ }\mu\text{m}$, which has been associated with adverse health impacts (Giunta, 2020).
6. The work zone contributes to motor-vehicle crashes (Yang et al., 2015), and a reduction in road construction can result in improved traffic safety, promoting public health by decreasing the number of motor-vehicle crashes. As discussed before, the CAVs impacts on transportation infrastructure needs are not clear, as are the CAVs second-order health consequences through the fifth and sixth pathways.

Quantifying the Impacts

The literature on the health implications of CAVs is speculative, consisting of qualitative analyses of CAVs health impacts, rather than quantitative analyses (Sohrabi et al., 2020). Quantifying the health impacts of CAVs can help to assess the extent of their impact and address the uncertainties in their implications, as mentioned in previous sections. In addition, quantification is required to evaluate supporting policies and make more informed decisions on CAV implementations. Despite attempts to estimate CAVs health impacts (Pourrahmani et al., 2020), quantitative literature is still in the nascent stages, potentially because of the complexity of the problem. Quantifying CAVs health impacts involves interdisciplinary research, which requires integrating information, data, techniques, tools, and concepts from various fields of expertise to be able to tackle the complexity of the problem. In this section, I reviewed recent literature regarding the health-impact assessment (HIA) of transportation projects, discussed CAVs first-order health impacts and illustrated a roadmap and future requirements for quantification purposes.

HIA is used to measure and evaluate the potential health effects of policies, plans, or projects on the community, either quantitatively or qualitatively (Cole et al., 2019). There is an increasing amount of information on quantitative full-chain HIA of transportation projects and policies (Nieuwenhuijsen et al., 2017). Full-chain HIA integrates a set of tools and models to assess the health impacts of transportation projects from the source (Nieuwenhuijsen et al., 2017). Using a similar approach, the CAV implementation and recommended supporting policies can be evaluated. Fig. 3 shows the required workstream for full-chain quantitative HIA of CAVs (first-order) health impacts.

First, scenarios regarding the CAV implementation and supporting-policy need to be defined, considering stakeholder insights and needs, CAV technologies and their functionality, and CAV adoption rate. Next, changes in transportation need to be estimated for each scenario, based on the seven transportation points of impact. Travel demand modeling is the main workstream for ascertaining the extent of changes in transportation along with urban growth modeling and crash prediction modeling. CAVs roles in providing mobility options for individuals with disabilities and non-licensed drivers can be estimated after quantifying the changes in trips and mode choice. The reduction in transportation-related jobs is also dependent on changes in VMT and traffic safety (vehicle service-related jobs). Finally, the burden of disease estimation of the scenarios consists of three steps. First, the exposure of the population to environmental health determinants needs to be estimated. Among the fourteen transportation-related risk factors, GHG, air pollution, noise, and heat require further modeling. Second, the health risk estimations for each risk factor can be found using the exposure–response function from the epidemiology studies. Third, the estimated risks for each scenario should be compared with those of the base scenario (e.g., no-automation scenario) to evaluate the health implications of CAV implementation or supporting policies (Fig. 3).

Quantifying the second-order health impacts can be even more challenging, given higher levels of uncertainty stemming from CAVs mechanisms of impact and the complexities regarding potential health consequences.

Policy Recommendation

The potential negative health impacts of CAV implementation have been discussed in the previous section. Decision-makers, law-makers, the automobile industry, the health sector, transportation engineers, and urban planners need to intervene to mitigate these negative impacts. The required policies to govern the negative impacts of CAVs can be categorized into four groups: (1) those needed to govern the CAVs unintended implications, (2) those that regulate the emissions from CAVs themselves and exposure to them, (3) those to incentivize technologies and mobility advancements to support CAV implementation, and (4) those to promote research on CAVs implications. Table 1 summarizes the recommended policies.

Urban sprawl, the modal shift from transit and active transportation, and the induced demand after CAV implementation are major contributors to the increase in VMT and its negative health implications. Therefore, well-thought-out policies are required to

Figure 3 Suggested workstream for quantifying CAVs health implications.

control these issues. In addition, a gradual transition to CAVs mitigates the social and health impacts of job losses, as it enables workers displaced by automated driving technology to develop new skills and find new jobs ([Center for Global Policy Solutions, 2017](#)).

Regulating CAV-related emissions and exposure to them is another effective policy to mitigate CAVs health implications. In particular, policies are required to regulate CAVs noise emissions, exposure to EMFs, and substance abuse in CAVs. Promoting organ donation can also mitigate the potential shortage in organs donors in case of a reduction in motor vehicle crashes. Supporting policies to control the spread of communicable diseases can mitigate the negative health impacts of shared CAVs.

Using shared CAVs instead of privately owned CAVs can reduce the expected growth in VMT ([Fagnant and Kockelman, 2014](#); [Greenblatt and Shaheen, 2015](#); [Krueger et al., 2016](#)) and parking needs ([Zhang et al., 2015](#)). Therefore, the negative health implications of CAVs attributable to increases in VMT can be alleviated. Equipping CAVs with electric engines that produce less harmful vehicle emissions ([Buekers et al., 2014](#)) and contaminants, such as engine oil, can also reduce the negative impacts of CAVs on public health.

Finally, providing financial support for future research on the identification and quantification of CAVs health implications can promote the discussion regarding CAVs health impacts, lead to more informed decision-making regarding CAVs supporting policies, and result in more efficient implementations of this new technology. Specifically, future research is required to address the uncertainties regarding CAVs implications, with a focus on their health impacts.

Table 1 Recommended CAV supporting policies

Recommended policy		Pathway to health
Govern the negative impacts of CAVs on transportation and land use	Control urban sprawl	Access Social exclusion Contamination GHG Community severance Heat Noise Air pollution Green spaces Physical inactivity
	Control modal shift and induced demand	Contamination GHG Community severance Heat Noise Air pollution Physical inactivity
	Support job losses by a gradual transition to CAVs	Social exclusion
Regulate exposure to CAV-related emissions	Control noise emission	Noise
	Regulate substance abuse for CAVs	Motor vehicle crashes
	Promote organ donation	Organ donation
	Regulate exposure to EMFs	EMF
	Control communicable diseases spread in shared CAVs	Communicable disease
Incentivize the use of supporting technologies	Support the use and advancements in elective vehicles	Noise Air pollution GHG Heat Contamination
	Support shared CAVs	Contamination GHG Community severance Heat Noise Air pollution Physical inactivity
Research on CAVs implication	Support research to quantify the CAVs health implications and address the uncertainties in the impacts	Green spaces ^a Physical inactivity ^a Noise ^b Community severance ^c Heat ^c Green spaces ^c

^aFrom changes in land use and built environment.

^bFrom changes in traffic flow.

^cFrom changes in transportation infrastructure.

Conclusion

CAVs can have a significant effect on public health. Considering the first- and second-order health impacts of CAVs, 32 and 6 pathways between CAV implementation and public health were identified, respectively. CAVs can negatively impact public health through 19 pathways, and their impacts are uncertain through 10 pathways. This indicates the necessity for supporting policies to govern the CAVs negative health implications. Furthermore, the uncertainties regarding CAVs implications and policy

recommendations require further quantitative evaluation. This is interdisciplinary research that requires integrating information, data, techniques, tools, and concepts from various fields of expertise. Full-chain health impact assessments can help overcome the complexity of the problem and evaluate CAV implementation and supporting policies. Further research is required to address the limitations in the literature regarding CAVs health implications by (1) identifying CAVs impacts on the freight transport system, (2) investigating CAVs impacts in rural areas, (3) quantifying CAVs health impacts, and (4) evaluating the recommended policies to govern CAVs negative impacts.

Introduction

Electric vehicles (EVs) represent changes in both vehicle and fuel technologies from conventional internal combustion engine (ICE) vehicles. EVs are propelled partly or solely by one or more electric motors, using energy stored in rechargeable batteries. There are three major types of EVs: battery electric vehicles (BEVs), fuel cell electric vehicles (FCEVs), and plug-in hybrid electric vehicles (PHEVs). BEVs run only on electricity stored in batteries that can be recharged by the electrical grid. FCEVs also run only on electricity stored in batteries, but the electricity comes from hydrogen stored on the vehicle that is converted by fuel cell. Because BEVs and FCEVs do not have tailpipe emissions, they are sometime referred to as zero-emission vehicles. PHEVs are similar to BEVs, but in addition to batteries and electric motor(s), a PHEV also has a fuel tank and an ICE. PHEVs can run solely on electricity, during which there will be no tailpipe emission. But they can also be propelled by the ICE as in conventional gasoline or diesel vehicles when the battery is depleted. During that time, PHEVs will produce tailpipe emissions like how conventional vehicles do. Replacing the ICE with one or more electric motors results in a more energy-efficient vehicle powertrain. For instance, EVs convert over 77% of electrical energy from the grid to power the wheels whereas conventional gasoline vehicles only convert 12%–30% of energy from the fossil fuel ([U.S. Environmental Protection Agency, 2020](#)). Therefore, EVs provide significant energy efficiency and associated greenhouse gas (GHG) reduction benefits over conventional ICE vehicles.

In recent years, the impetus for EVs came from the climate target adopted in the 2015 Paris Agreement to limit the rise of the global temperature well below 2°C above the preindustrial level ([Rogelj et al., 2016](#)). To achieve this target, one of the several measures recommended by the International Energy Agency (IEA) is that at least 20% of all on-road vehicles be driven electrically by 2030. Several countries and jurisdictions have started to act on the IEA recommendation. For instance, California is leading the push in the United States to achieve zero-emission transportation. In response to state-mandated GHG emission targets, including 40% below 1990 level by 2030 and 80% below 1990 level by 2050, California has adopted a variety of incentives and regulations, such as providing EV purchase incentives for individuals and fleets, permitting single-occupant EVs to use carpool lanes, imposing EV sales mandates on vehicle manufacturers of both cars and trucks, and requiring public transit agencies to transition to 100% zero-emission bus fleets, among others.

Global cumulative passenger EV sales have grown exponentially, surpassing 4 million in fall 2018. China was driving this trend where it accounted for 37% of all passenger EV sales in the world since 2011, and around 99% of electric bus sales ([Bloomberg NEF, 2018](#)). With the rapid rise in sales, global passenger EV fleet is forecast to reach 500 millions by 2040, making up 31% of the world's passenger cars on the road ([Bloomberg NEF, 2020](#)). Early adopters of EVs, at least in Sweden and Germany, tend to be predominantly male, young, wealthy, and college-educated ([Langbroek et al. 2017](#); [Plötz et al., 2014](#)). In the United States, a survey of 1,094 people in San Francisco found that people with household income more than \$200,000 are 7% and 13% more likely to adopt BEV and PHEV, respectively, compared to people with household income less than \$75,000 ([Spurlock et al., 2019](#)). In the medium-duty sector, early adopters of EVs tend to be large fleets that utilize EVs in applications such as package delivery, fixed route transit, school bus, and utility ([Gladstein et al., 2020](#)). While heavy-duty EVs have not been fully adopted, there have been recent demonstrations of heavy-duty EVs in short haul applications such as drayage and regional distribution ([California Air Resources Board, 2020](#)).

Vehicle Emissions

Emissions associated with vehicles can be evaluated on a direct as well as a life-cycle basis. Direct emissions are emitted through the tailpipe, through evaporation from the fuel system and during the fueling process, and from brake and tire wear. Direct emissions include smog-forming pollutants (such as nitrogen oxides and volatile organic compounds), other pollutants harmful to human health (such as particulate matter and carbon monoxide), and GHGs, primarily carbon dioxide (CO₂). BEVs and FCEVs produce no direct emissions (except for from brake and tire wear), which specifically helps improve air quality in areas where they are used. On

Figure 1 Average mix of electricity generation sources and annual life-cycle CO₂ emissions per vehicle in California, United States (U.S. Department of Energy, 2020b).

Figure 2 Average mix of electricity generation sources and annual life-cycle CO₂ emissions per vehicle in West Virginia, United States (U.S. Department of Energy, 2020b).

the other hand, PHEVs produce evaporative emissions from the fuel system as well as tailpipe emissions when operating on the ICE. However, because most PHEVs use smaller ICE and are more efficient than comparable conventional vehicles, they still produce lower tailpipe emissions even when operating on the ICE (U.S. Department of Energy, 2020a).

In addition to direct emissions produced during vehicle use, life-cycle emissions also include emissions associated with the production, processing, distribution, and recycling or disposal of vehicle and fuel. For example, for a conventional vehicle that uses gasoline as fuel, emissions are produced not only when gasoline is burned in the vehicle, but also when petroleum is extracted from the ground, refined into gasoline, and distributed to gas stations (U.S. Department of Energy, 2020a). Because of the broader scope, life-cycle emissions include more variety of harmful pollutants and GHGs beyond those included in direct emissions. For example, petroleum refining process also produces sulfur dioxide and chlorofluorocarbons (Liu et al., 2020).

All vehicles produce a large amount of life-cycle emissions. However, EVs typically produce lower life-cycle emissions than conventional vehicles because most emissions are lower for electricity generation than burning gasoline or diesel. The exact amount of these emissions depends on the mix of electricity generation sources, which varies by geographic location. Figs. 1 and 2 give examples of how the mix of electricity generation sources could significantly impact life-cycle emissions of EVs. According to Fig. 1, more than half of the electricity in California is generated from renewable sources such as wind and solar. Therefore, EVs in California have low life-cycle CO₂ emissions. On the other hand, Fig. 2 shows that almost 95% of the electricity in West Virginia is generated from fossil fuels (coal and natural gas), which makes EVs there have relatively higher life-cycle CO₂ emissions. By comparison, an EV in West Virginia produces four times as much life-cycle CO₂ emissions as the same EV in California. As of 2015, driving an average BEV would result in lower CO₂ emissions than driving a comparable gasoline vehicle in many parts of the U.S. (Nealer et al., 2015). That is now true anywhere in the U.S. (U.S. Department of Energy, 2020b).

Environmental and Health Impacts of Electric Vehicles

In terms of environmental and health benefits, BEVs and FCEVs produce no tailpipe emissions, and thus, do not expose travelers (drivers, passengers, transit riders, bicyclists, pedestrian, etc.) as well as people who live, work, or play near roadways to harmful

pollutant emissions as conventional ICE vehicles do. Exposure to these pollutant emissions has been associated with a variety of respiratory and cardiovascular diseases. Health damages from such pollutant exposure were estimated to range from 1.38 to 1.48 cents per vehicle miles traveled. Thus, replacing a conventional ICE vehicle with a BEV or a FCEV would result in approximately \$1,477 to \$1,893 (in 2015 U.S. dollars) of societal health benefits over the life of the vehicle or 120,000 miles (Malmgren, 2016). A modeling study of the Greater Toronto and Hamilton Area in Canada reveals that a shift to EVs would lead to cleaner air, save lives from respiratory and cardiovascular diseases, and provide billions in social benefits every year. The modeling results show that each BEV and FCEV that replaces a conventional gasoline vehicle would bring \$9,850 (in 2016 Canadian dollars) in social benefits from avoiding premature deaths, which is far higher than the \$5,000 purchase incentive per vehicle currently offered by the Canadian government (Environmental Defence and the Ontario Public Health Association, 2020). In addition, it is argued that the health benefits of EVs also justify the use of government incentives to build EV charging stations in support of the growing EV population (House and Wright, 2019).

BEVs and FCEVs producing no tailpipe emissions also has a side benefit in that there will be no chance of carbon monoxide poisoning, which has led to several deaths in the U.S. (Jean and De Puy Kamp, 2018). This can occur if leaving conventional ICE vehicles on in closed space (such as garage) for a long period, resulting in heightened level of carbon monoxide emission, which is odorless and colorless. Since BEVs and FCEVs require no gasoline or diesel, there will also be less exposure to evaporative emissions in garage and at gas station. While EVs still produce brake and tire wear emissions, they produce lower brake wear emissions than their conventional counterparts due to the regenerative braking technology that allows EVs to use brake pad less often. Other benefits of EVs include reduced noise pollution, faster acceleration and smoother ride, improved safety (as EVs tend to have lower center of gravity and so be less likely to roll over), lower maintenance costs, and reduced energy dependence (as electricity can be generated domestically).

On the other hand, emissions footprint of EVs also depends on how the electricity that powers them is generated. The increased demand for electricity to serve EVs may increase emissions at power plants (Nopmongkol et al., 2017). Electricity utilities often have peaker plant, which is supplemental power plant that operates only when demand for power is high. Peaker plants usually run on natural gas, and not on renewable energy sources. While natural gas power plants are cleaner than coal-fired power plants, they still emit a significant amount of nitrogen oxides and other emissions, which impacts the nearby communities. This means emissions are simply shifted from where EVs are driven to the power plants that generate electricity for these EVs, potentially resulting in environmental injustice. For example, while only 42% of the electrification in California comes from natural gas, half of the natural gas power plants in the state are concentrated in some of the most environmentally disadvantaged communities that are already overburdened with pollution. However, this will not be the case if the electricity that serve EVs is generated from renewable sources such as wind and solar.

In the life-cycle of a BEV that also includes its manufacturing and disposal, other important sources of emissions are the production of the battery and the vehicle itself (Tessum et al., 2014). Weis et al. (2016) compared BEVs and conventional gasoline vehicles, and found that BEVs have higher sulfur dioxide but lower carbon monoxide and volatile organic compound life-cycle emissions. Also, reduced direct emissions of nitrogen oxides from increased adoption of EVs may initially cause unexpected increase in secondary pollutants such as ozone and secondary particulate matter. Because of nonlinear production chemistry and titration of ozone, reduced nitrogen oxides could result in ozone enhancement in urban areas, further increasing the atmospheric oxidizing capacity and secondary particulate matter. This phenomenon has occurred in many cities around the world during the COVID-19 pandemic (Le et al., 2020). In addition, in the early days EVs used to cause unexpected safety issues because they were very quiet, making pedestrians and bicyclists unaware of their presence. Regulators in many countries have required or will be requiring EVs to generate warning sounds while traveling at low speed.

Discussion and Conclusions

BEVs and PHEVs make up the majority of EVs on the road today. While FCEVs are commercially available, they have not gained the same level of market acceptance and wide adoption as BEVs and PHEVs. This trend is expected to continued in the next few decades. The rapid growth in EV population has been contributed by a variety of EV-related incentives and regulations, which have spurred innovations (especially in battery technologies) that drive down the cost of EVs. It is anticipated that the price of a passenger EV will be in parity with a comparable ICE counterpart in the next few years. Modeling studies have shown significant environmental and health benefits of a large adoption EVs. As there are more and more EVs on the road, it will be interesting to observe these benefits of EVs in real world.

While passenger EVs have largely overcome market barriers over the last decade—they now have respectable driving range while also being more affordable—EV buses and trucks are currently going through that phase. Early adoptions and demonstrations of these heavier EVs have proven their technical and operational feasibility in many applications such as urban transit and short haul. However, it will still require further advancement in battery and charger technologies to make EV buses and trucks economically attractive, as compared to their ICE counterparts and other alternative fuel options. But once that becomes materialized and a large fraction of medium-duty and heavy-duty vehicles also turns into EVs, the environmental and health benefits to the society will amplify.

It is important to keep in mind that EVs need clean electricity from renewable sources in order to minimize their life-cycle emissions and ensure that the emissions and health impacts are not simply shifted from where EVs are used to communities near

power plants. And while EVs can help address many of the energy, climate, environmental, and public health issues, they will not solve traffic congestion problems. Therefore, a holistic approach that not only promotes a full transition to EVs and renewable energy sources but also manage whether, where, when, and how we travel should be taken in order to achieve a truly sustainable transportation future.

Introduction

The shared economy concept has expanded through different sectors and business models, bringing innovative solutions that can reshape people's and access to services (Cohen and Kietzmann, 2014; Cherry and Pidgeon, 2018). Amid shared economy models, the shared mobility modalities have grown in urban areas by providing more sustainable and affordable transportation services (Cohen and Kietzmann, 2014; Machado et al., 2018). In addition, shared mobility services bring economic opportunities by creating new space for profit and employment (Cherry and Pidgeon, 2018).

Although shared mobility has been extensively studied in recent years (Cohen and Kietzmann, 2014; Machado et al., 2018; McKenzie, 2020), the intersection among shared mobility and health subjects was not widely researched yet. This article discusses how shared mobility can help reduce respiratory and cardiovascular diseases in regions with dense traffic, and presents benefits and challenges of providing shared mobility services for vulnerable groups. The studied vulnerable groups were older people in rural areas far from healthcare services, people with physical or developmental disabilities, people living close to wildfires and needing to be evacuated, and low-income people in the status of transport-related social exclusion.

In order to illustrate the captivating multidisciplinary nature of this work, a word cloud was generated to visualize general subjects among the referenced works. Word cloud is a visual representation of words from a text, enhancing the most frequent words (Heimerl et al., 2014). In this case, the word cloud was built using all abstracts from the referenced works in the sections "Traffic-Related Pollution and Noise" and "Inclusive Transport." Referenced reports which do not have an abstract were represented by their first section inside the "Executive Summary" chapter. Referenced short papers with no abstract nor an equivalent section were represented by their first paragraph. Referenced abstracts or first section from "Executive Summary" chapter written in Portuguese or in British English were translated to American English. It was necessary to avoid replicas of the same word. Word replications varying only upper or lower case, and differing only in plural or singular were also eliminated. After these corrections, the word cloud was composed using 13,622 words, of which 2,798 words are unique. Fig. 1 shows the word cloud generated using the website "wordclouds.com" with default settings.

The words "air," "noise," "pollution," "exposure," "traffic" probably appear more often because they together summarize the causes of health issues caused by fossil-fueled vehicles, presented in the section "Traffic-Related Pollution and Noise." The words "access" and "disabilities" seem to represent the section "Inclusive Transport." Words related to the section "Traffic-Related Pollution and Noise" appeared more often than words related to the section "Inclusive Transport," probably because most references about exposure of traffic-related noise also evaluate the exposure of traffic-related air pollution, since both factors can occur together and be correlated. The topics about "Inclusive Transport" seems to be more extended through different subjects, therefore words are repeated less. Other smaller words on the word cloud evidence the particularities from the papers which compose the references of

Figure 1 Word cloud of referenced works.

this work. The following section presents the diseases caused by traffic-related air pollution and noise and presents environmentally friendly approaches to reduce those diseases. The subsequent sections, respectively, presents the transport-related social exclusion issues and discusses the computational challenges for the shared mobility opportunities.

Traffic-Related Pollution and Noise

This section is divided in four subsections: "Traffic-Related Air Pollution," "Traffic-Related Noise," "Active Transport," and "Electric Vehicles." The following subsection discusses the diseases caused by emissions of pollutants on air.

Traffic-Related Air Pollution

Amid the sustainable development goals addressed by the United Nations¹ there are the goals “Make cities inclusive, safe, resilient and sustainable” and “Take urgent action to combat climate change and its impacts.” Both goals aim to improve air quality in the city by diminishing emissions of carbon dioxide (CO₂) in order to reduce air pollution.

Air pollution is often related to adverse health outcomes in the population (Giles-Corti et al., 2016). These adverse outcomes include impaired lung development on prenatal child (Korten et al., 2017), childhood asthma (Gasana et al., 2012; (Khreis et al., 2019a, b; Alotaibi et al., 2019), childhood wheeze (Gasana et al., 2012), asthma exacerbation (Yang and Omaye, 2009), impaired lung function (Samet and Krewski, 2007), cardiovascular disease and mortality (Rajagopalan et al., 2018), and higher prevalence and risk of chronic kidney disease among the elderly population (Chen et al., 2018).

Furthermore, air pollutants from traffic and other combustion sources were associated with increased risk of infection by influenza (Croft et al., 2019). Recent works also associated air pollution with the vast diffusion of COVID-19 in the North Italy (Coccia, 2020; Conticini et al., 2020), and Wuhan, China (Yao et al., 2020). A prolonged exposure to air pollutants can induce a chronic respiratory system inflammation, even in young and healthy people, and weaken the subject's immune system. That may explain the higher prevalence and lethality of COVID-19, together with a higher average age of inhabitants in the North Italy region (Conticini et al., 2020).

The International Agency for Research on Cancer classified diesel engine exhaust as “Group 1 carcinogen,” known to be carcinogenic to humans². This classification was given after sufficient evidence that being exposed to diesel engine exhaust increases the risk of lung cancer (IARC, 2012). However, heavy-duty vehicles such as tractors, trucks, and buses usually are powered by diesel due to its relatively low-operational cost (Hannach et al., 2019). Furthermore, other fossil-fueled powered vehicles also emit air pollutants that are harmful to urban inhabitants and commuters (Mukaria et al., 2017; Anowar et al., 2017; CETESB, 2019; Nogueira et al., 2019).

Different urban environments have different amounts of pollutant particulate matter on air, making some places more harmful to the peoples' health than other places (Cheng et al., 2012; Targino et al., 2018; Nogueira et al., 2020). In Taipei, Taiwan, a study with measurements collected in July 2010 showed that the amount of fine particulate matter on air in the bus platform of the Taipei

¹ <https://www.un.org/sustainabledevelopment/sustainable-development-goals/>

¹ <https://www.cancer.org/cancer/cancer-causes/general-info/known-and-probable-human-carcinogens.html>

Bus Station was 2.0 times greater than the amount found on the waiting room, and 2.8 times greater than in the ambient monitoring station. Also, the station ticket inspectors were exposed from 1.6 to 1.8 times more fine particulate matter than in the Taipei outdoor atmosphere (Cheng et al., 2012).

In the city of Londrina, Brazil, a study with data collected from October through December 2014 showed that the concentration of black carbon inside buses was up to six times greater than on the outside of buses, for commuters walking or bicycling (Targino et al., 2018). Another study using measurements collected from May through December 2016 in the Metropolitan Area of São Paulo, Brazil, showed that commuters who wait for the bus in bus terminals on weekdays were exposed to 128% more coarse particulates than commuters who traveled outside the bus terminals. Besides, the concentration of black carbon on bus terminals was 3.3 times greater than in background sites (Nogueira et al., 2020).

Traffic-Related Noise

Traffic-related noise is known to be annoying and, therefore, it is also a decision factor while choosing where to live (Wardman and Bristow, 2004; Arsenio et al., 2006) since spatial characteristics such as traffic volume and length of nearby arterial roads can better explain the difference of noises in a city than temporal characteristics such as noise difference between workdays and weekends (Zuo et al., 2014). Furthermore, resting in a bedroom with a window facing a quieter traffic environment reduces the risk of sleeping problems (Bodin et al., 2015).

Besides the annoyance, traffic-related noise can bring psychological effects to people (Zuo et al., 2014). Those effects include sleep disturbance (Bodin et al., 2015), stress reaction (Dratva et al., 2010), hypertension (Fuks et al., 2017), cardiovascular events as consequence of physiological disorders (Recio et al., 2016), and diabetes (Clark et al., 2017). Also, traffic-related noise can increase the risk of myocardial infarction (Grazuleviciene et al., 2004; Babisch et al., 2005) and stroke (Münzel et al., 2018).

Children can also suffer the effects of traffic-related noise (Skrzypek et al., 2017; Foraster et al., 2019). A research based on 2715 children aged from 7 to 10 years, studying in 39 socioeconomically similar schools from Barcelona, Spain, showed that exposure to traffic-related noise outdoors was associated with smaller working memory and with greater inattentiveness, indicating that children exposed to traffic-related noise may have a slower cognitive development (Foraster et al., 2019). Another study with about 5136 children aged from 7 to 14 years old from Bytom, Poland, also found association between traffic-related noise and sleep disturbance for children exposed to the noise. The authors also found association between traffic-related noise and attention disorders (Skrzypek et al., 2017).

Air pollution and noise issues caused by fossil-fueled powered vehicles can be avoided during the city planning by setting homes, schools, facilities and other public areas far from dense traffic roads, and setting cycle lanes distanced from motor vehicle lanes (Giles-Corti et al., 2016). For the already built and working cities, common approaches consist in replacing fossil-fueled powered vehicles by active transport or electric vehicles. The following subsections present these approaches.

Active Transport

An approach would consist in shifting mobility from motor vehicles to active transport means, such as walking and bicycling (Nieuwenhuijsen and Khreis, 2016). Car-free and active mobility policies have grown through the recent years in order to promote more environmentally friendly and healthy cities. By doing so, it is possible to reduce road traffic fatalities (Otero et al., 2018), mitigate diseases with traffic-related air pollution or noise causes, and incentivize physical activities reducing the risk of diseases related to sedentarism (Nazelle et al., 2011; Nieuwenhuijsen and Khreis, 2016; Vich et al., 2019).

Practicing active mobility reduces the risks of cardiovascular diseases, diabetes, breast cancer (in women), colon cancer and dementia (Rojas-Rueda et al., 2013). Active mobility can also be based on the shared economy concept, creating services such as bikesharing. Bikesharing is an active shared mobility service which focuses on renting bikes on an as-needed basis (Machado et al., 2018; Cohen and Shaheen, 2018). Bikesharing can reduce congestion, bridge first-and-last-mile gaps in the transportation network and motivate multi-modal trips (Cohen and Shaheen, 2018).

Environmental factors can also motivate people to practice active mobility. A study with 127 participants sourcing 772 days of walking and location data in Barcelona, Spain, identified that while daily walking time was not statistically significant associated with participant's gender, employment status, or day type (workday or weekend), the participants' daily walking time was positively associated with existence of urban trees and large-scale open spaces such as beaches or large parks (Vich et al., 2019).

Regarding cyclists from places without car-free policies or lacking environment friendly spaces, their exposure to air pollution can be reduced by making healthier and preferred alternative routes. Although these routes may be longer, a reasonable trade-off between distance and cleaner air can be found by avoiding areas with concentration of pollutant particulate matters, for example (Anowar et al., 2017). Other approaches for improving health-related quality of life focus on replacing the fossil-fueled powered vehicles by other less pollutant ones. The following subsection presents the benefits of using electric vehicles.

Electric Vehicles

A direct benefit of replacing fossil-fueled powered vehicles by electric ones relies on reducing the transport-related air pollution. As an example, Nogueira et al. (2020) showed that renovating the diesel bus fleet of the Metropolitan Area of São Paulo by replacing the

buses with standard Euro II engines by buses with standard Euro V engines, and incorporating electric buses, would reduce CO₂ and nitrogen oxides (NO) emissions by up to 40%.

Incorporating electric vehicles on the cities is a promising way of reducing the carbon emissions on air (Ji et al., 2012; Nogueira et al., 2020). Even in regions where the electricity production consumed by the electric vehicles was generated from fossil-fuels, that production can happen far from urban centers, diminishing the inhabitants' health diseases caused by air pollution. Besides, there are electric vehicles planned for only one passenger, such as e-scooters. The electricity consumption for these vehicles is lower than the consumption of an electric car, avoiding the waste of produced electricity whether there is only one passenger per vehicle (Ji et al., 2012). Furthermore, electric vehicles can be offered as a mobility service following the concept of shared mobility. With shared mobility, the number of idle vehicles through the day can be reduced, not even needing to produce unnecessary vehicles. By doing so, it is possible to make mobility more sustainable (Machado et al., 2018).

An online survey disseminated in different Spanish cities between April and June 2018 identified the profile of e-scooter short-term rental clients. Analysis showed patterns of sociodemographic data, such as lower age and university degree, on more frequent clients (Aguilera-García et al., 2020). New lifestyle trends are also noticed in India, with more environmental concerns related to the rapid urbanization and increase in the middle-class population (Roy et al., 2018). Therefore, shared on-demand transport services together with sustainable awareness and low-cost necessities are shaping the emergent transportation modes in the cities (Machado et al., 2018; Roy et al., 2018; Aguilera-García et al. 2020). The following section presents the drawbacks caused by the lack of such services.

Inclusive Transport

According to the Social Exclusion Unit (2003) from the United Kingdom, transport problems can hamper people's access to services and opportunities, reinforcing their status of social exclusion. The lack of transportation means can also bring difficulties to build social networks and reduce family recreational day trips, being harmful to well-being and mental health. Few mobility options can also restrict people to walk to locally accessible grocery stores, being subject to higher grocery prices and having fewer healthy food options. Besides, the lack of transportation means can hamper opportunities of employment, education, and training that could increase income (Mackett and Thoreau, 2015).

The authors from Social Exclusion Unit (2003) defined transport accessibility as people being able to get to key services at a reasonable cost, in reasonable time and with reasonable ease. Also, accessible transport should be reliable, passengers should feel safe using it and people should be financially and physically able to access the transport. Low-accessibility transportation can cause problems for work, learning, healthcare, shopping, social, and sporting activities.

Transport-related social exclusion is often more properly explained by non-transport factors and issues of power, accessibility, and choice. For example, while people with money, time and good health to drive can choose to enjoy an attractive rural environment, inhabitants of these rural areas (lacking services such as healthcare and shopping) can be "forced" to own and maintain a vehicle in order to have access to essential services. Therefore, being "forced" to have a vehicle is a factor of experiencing transport-related social exclusion, differently from choosing to own a vehicle while having other reasonable options of mobility (Pooley, 2016).

Shared mobility modes represent a promising set of solutions for vulnerable groups that are not properly served by public transport (due to waiting time, trip duration or distance to get to a bus stop) neither can comfortably afford a private vehicle (Viegas and Martinez, 2017). The shared mobility concept can also be applied to evacuation situations (Li et al., 2018; Wong and Shaheen, 2019).

Shared Mobility on Emergency Evacuations

An online survey distributed to people impacted by the wildfires of October 2017 in Northern California, December 2017 in Southern California, and August 2018 in Carr evaluated the respondents' willingness to share transportation and shelter in future evacuations. Results showed that respondents are more likely to share transportation resources than housing resources due to the lesser level of commitment with the individual being helped. Thus, shared mobility through community aid can play a key role on saving lives during emergencies (Wong and Shaheen, 2019).

However, among those three wildfires, the percentage of respondents willing to share personal transportation while evacuating varied from 59% to 72%, and the percentage willing to share personal transportation before evacuation varied from 37% to 62%. Fewer respondents willing to offer transportation before evacuation is explained by the possible short time for preparation between the risk recognition of wildfire and the beginning of evacuation. Also, more than 30% of respondents from each evaluated wildfire stated that they would deviate at maximum ten minutes from evacuation route to pick-up a passenger (Wong and Shaheen, 2019). Even though ridesourcing services such as Uber and Lyft could play a major role during evacuations, respondents from vulnerable groups (older adults, individuals with disabilities and low-income individuals) expressed strong concern about ridesourcing availability and reliability with enough accommodation for disabled people or at a affordable cost (due to possible dynamic pricing) mainly in areas near the fire line (Li et al., 2018; Wong and Shaheen, 2019).

Older people from the wildfire areas said not to trust in the ridesourcing drivers and were highly concerned about their personal security, particularly while sharing rides. They also noted that drivers may need to evacuate their own families or be unwilling to help

in the evacuation process. People with disabilities were concerned about ridesourcing vehicles not being wheelchair accessible nor have enough space to store the wheelchair. Also, it is possible that drivers cancel trip requests after realizing the passenger's disability. Besides, ridesourcing drivers may not know how to assist people with disabilities, nor be trained to save people in a disaster. A proposed solution consisted in maintaining a neighborhood volunteer network similar to carpooling, creating partnerships with paratransit services, training drivers to identify and assist people with disabilities, focusing on drivers who live near but not in the areas which can be impacted by a wildfire, receiving support from government, and ensuring that mobility costs will not surge during the evacuation (Wong and Shaheen, 2019).

Mobility for People With Disabilities

Even without disasters and with a reasonable number of mobility options, people with disabilities can also be transport-related and socially excluded. Besides individuals with physical disabilities, people with developmental disabilities (including individuals diagnosed with autism spectrum disorder, cerebral palsy, intellectual disability, or traumatic brain injury) can also face barriers while using transportation means (Stock et al., 2011; Lubin and Deka, 2012; Wasfi et al., 2017). These barriers include lack of awareness of transport options (Wasfi et al., 2017; Stock et al., 2019), having to understand complex schedules of public transport or potential difficulty of transfers (Wasfi et al., 2017), need of advance scheduling for using demand-responsive paratransit services and difficulty on understanding onboard announcements (Lubin and Deka, 2012), high expenses in ridesourcing since people with developmental disabilities are less likely to have a driver's license or own a private vehicle, and issues of personal safety and security such as encountering with strangers, getting lost or passing by busy street crossings (Stock et al., 2011).

Proposed ways to mitigate those issues consists in training people with developmental disabilities to use specific technologies to simplify and guide them to get to their destinations. As an example of these technologies, there are navigation apps explaining with pictures and audios the next steps of using public transport, such as when to signal a stop and drop-off the bus (Stock et al., 2011; Stock et al., 2019). In the future, autonomous vehicles can enable less expensive ridesourcing services that could also reduce barriers of transport-related exclusion for low income individuals with disabilities (Rodier, 2020). Besides low income individuals with disabilities, autonomous vehicles can also reduce the gender gap in transport-related social exclusion (Singh, 2019).

Gender and Rural Barriers of Mobility

Transport-related social exclusion may have different impacts according with gender, since women are usually more concerned with their personal safety and security, and they are less likely to have a driver's license (Mackett and Thoreau, 2015; Singh, 2019). Regarding older people in rural areas, a study performed in the Republic of Ireland and Northern Ireland showed that although older men usually have a driver's license, their lifestyles make them more car dependent than old women without a driver's license and without a husband. Most of the men participating in that study wanted to be more independent in their trips, were not used to sharing transport space, and saw community transport as "feminised." The "feminised" stereotype is due to rural transport services being predominantly used by women to get to services more attractive to them, such as shopping and visiting clubs and social groups. The study also showed that since health services are usually centralized in order to provide better medical facilities and services, some rural areas have no transport network to access these services. In this case, patients are car-dependent to get to, at least, the first transfer to reach the medical facility. This problem affects both older males and females. Even when someone is able to drive (has a driver's license, a car, and is healthy to drive), his spouse or relative may not be able to drive and may need help, since rural areas commonly do not have a cheap taxi service available (Ahern and Hine, 2012).

Mobility for Older People During COVID-19

Regarding regions with public transport or shared mobility options, an important point about clients' health rely on cleaning the shared vehicles, mainly during epidemic scenarios such as from COVID-19. Since shared vehicles are expected to be reused by other clients (Machado et al., 2018) and viable COVID-19 virus were detected in plastic or stainless steel surfaces even after 72 hours of exposure (van Doremalen et al., 2020), the contamination by COVID-19 can spread through clients of shared mobility even if they used the same vehicle on different days.

Being contaminated by COVID-19 is dangerous mainly for older people. A study from Mainland China with data from 44,672 contaminated people as of February 11, 2020 showed that although 13,909 people with COVID-19 were at least 60 years old (equivalent to 31%), most of deaths (829 from 1023 deaths, equivalent to 81%) occurred to people at least 60 years old (Novel Coronavirus Pneumonia Emergency Response Epidemiology Team, 2020). About Italy, another study with data as of March 15, 2020 showed 22,512 confirmed cases and 1,625 deaths, of which 1,567 (equivalent to 96%) are from people who are at least 60 years old (Livingston and Bucher, 2020). Given the higher risks related to older people being contaminated by COVID-19, together with health complications of people with chronic diseases (such as respiratory system inflammation mentioned earlier in this work), it is expected that individuals in the risk group avoid using carpooling options or public transport for health reasons, and therefore can establish or reinforce their status as transport-related socially excluded people.

Computational Challenges

The availability, costs and company profits of different mobility services under diverse scenarios can be simulated using software (Mourad et al., 2019; Lage et al., 2019; Monteiro et al., 2019a). However, although the way such software is built can make them run faster and be more computationally efficient (Mourad et al., 2019; Monteiro et al., 2019b), some of those mobility problems become hugely complex as wider and more realistic scenarios are evaluated. In these cases, an impracticable time (in the order of years) would be required to find the best solution among all the possible ones (Garey and Johnson, 1979; Cormen et al., 2009).

Usually, extensive and realistic problems are dealt with using methods which do not guarantee that the solution achieved is the best among all possible. However, a computer running these methods can quickly find a good solution, and that found solution may often be reasonable for the problem at hand (Mourad et al., 2019). Nevertheless, as the problem becomes more complex, it becomes harder to find a good solution in a viable time (Ritzinger et al., 2016). This can become a challenge for companies of shared-mobility services, which may daily depend on such simulation or optimization software, since their prices are usually constrained by the prices of competitors. As an example, carsharing rentals should be lower than ridesourcing, otherwise the clients would prefer to simply call an Uber instead of having to walk to get to an available vehicle and also having to drive to their destination (Monteiro et al., 2019a).

Similar situations emerge while adopting the sustainable and inclusive services mentioned in the chapters “Traffic-Related Pollution and Noise” and “Inclusive Transport.” Planning the location of electric vehicle chargers is within the class of the hardest problems of Computer Science (Lam et al., 2014). This class is known as NP-Hard (Garey and Johnson, 1979; Cormen et al., 2009), which also contains the problem of optimizing the routes carried by a vehicle relocating shared bikes in order to bring them to areas of demand (Erdoğan et al., 2015). In addition, the NP-Hard class contains the problem of optimizing multiple workers to relocate (or consequently give maintenance and clean) the carsharing vehicles (Albinski, 2015), and it is also known that the carpooling problem proposed as a solution for community evacuation belongs to the NP-Hard class (Buchholz, 1997; Baugh et al., 1998). Regarding community evacuation, carpooling would have an additional hindrance, related to the probably short response time available to make decisions (Mourad et al., 2019) to save people in more isolated areas.

Other computational challenges can emerge in tasks of acquisition, processing and analysis of data. The lack of quality and enough observations in datasets about Vulnerable Road Users (VRU), particularly from developing countries, hamper the use and trust of standard spatial regression models in VRU analysis (Machado et al., 2015). Other problems happen while analyzing data from traffic accidents. Although public datasets of traffic accidents can be available about the same area, each of these datasets (official and unofficial) can present different traffic accident events, requiring that data integration techniques be applied to merge those data before analyzing them (Santos et al., 2017). In addition, low precision of georeferenced data about moving objects, such as vehicle GPS location history, can require preprocessing tasks in order to avoid analyzing abnormal locations recorded due to GPS errors (Monteiro et al., 2017).

Final Remarks

Besides the difficulty of finding good solutions and dealing with quality and integration of data, some services have additional challenges to be properly deployed by for-profit companies due to the involved costs. For example, organizing the staff to clean the vehicles between rentals in order to reduce the risks of contamination by diseases such as COVID-19 would require higher costs than only relocating vehicles according to demand. Also, offering accessible transport modes in rural areas with low demand requires more vehicle and operational costs than only serving the frequent trips. However, for these examples of contamination and rural areas, shared mobility modes can be more suitable than conventional public transport since buses and subway can easily spread contamination due to the people's agglomeration, and buses and subways are restricted to fixed routes and schedules. Furthermore, the additional cost for shared mobility could be overcome by community aid or support from the government.

Concluding, shared mobility acts as a promising source of trips, benefiting people in vulnerable groups, and enabling them to access essential services, such as healthcare. Shared mobility services can also reduce the number of vehicles in the cities, making them more sustainable, and healthy for all inhabitants. Fewer vehicles transiting, mainly regarding the fossil-fueled powered ones, can make the air cleaner and the environment less noisy, improving urban quality of life.

Introduction

Bike-sharing systems (BSSs) have been implemented in several cities around the world as policies to mitigate climate change, reduce traffic congestion, and promote physical activity and thereby health. Also, the cyclists do not produce air pollution or traffic noise and help toward the last mile trips. A BSS or bike-share scheme is a system in which bikes are made available for shared use to individuals on a very short-term basis. Often the time use is limited to allow multiple users per bike and rapid turnaround. BSS allow people to borrow a bike from one point and return it to a different point (**Fig. 1**). BSS has become very popular in cities across Europe, Asia and America, and in 2013 more than 500 BSS were implemented around the world (**Larsen, 2013**).

Interest in urban cycling is increasing and the number of bike share programs has grown rapidly over the last 5–10 years. Bike share programs have existed for almost 50 years, but the recent change in the technology used and interest in more active and liveable cities has a more widespread use of the programs. Wuhan and Hangzhou, China currently have the world's largest public bicycle share schemes, with 70,000 and 65,000 bikes, respectively (**China News, 2011**; **Meddin, 2011a**). In 2007, Paris launched Europe's largest scheme, with over 20,000 bicycles. New York City launched North America's largest bike share program, with 10,000 bicycles in 2013. **Shaheen et al. (2010)** summarize the benefits of bike sharing as flexible mobility, emission reductions, physical activity benefits, reduced congestion and fuel use, individual financial savings and support for multimodal transport connections. These factors have acted as a catalyst for the development of bike sharing globally.

The first bike share began in Europe in 1965 with fairly simple technology and the first large-scale bike-sharing program was launched in 1995, in Copenhagen as Bycyklen (City Bikes) with 1100 bikes (**Shaheen et al., 2010**). Currently the BSS in Paris called "Vélib", is the biggest in Europe with 23,600 bikes and 1800 stations; other BSS have also reached a considerable large size as London (12,000 bikes), Barcelona (6000), Lyon (4000) or Valencia, Seville, Milan or Brussels with more than 2000 bikes. In some countries like Spain, there has been a rapid increase in the number of BSS, almost doubling the number of systems implemented from 58 to 97 between 2008 and 2009 (**Oortwijn, 2015**). But China still has the largest system as mentioned before. Either way the presence of BSS can be found around the globe (**Fig. 2**).

Bike share programs can provide safe and convenient access to bicycles for short trips, such as running errands during lunch, and transit-work trips. Users do not need parking at their home and maintenance of the bikes is taken care of making it convenient for the users. Until recently, bike share programs worldwide had experienced limited success; in the last 5–10 years, innovations in technology have given rise to a new (third) generation of technology-driven bike share programs. These new bike share programs can dramatically increase the visibility of cycling and lower barriers to use by requiring only that the user have a desire to bike and a credit card or phone.

Bike share programs help increase cycling mode share, serve as a missing link in the public transit system, reduce a city's travel-related carbon footprint and provide additional "green" jobs related to system management and maintenance. They have had limited success though to get people out of the car and onto the bike; to a large extent new users are coming from the public transport system or previously walked. In the US, many cities are looking into bike share programs, but they have not yet been widely implemented. The US has a strong car dependency and limited infrastructure for cycling which makes it harder. Some recent systems failed and were abandoned. Poor design, underutilization and a lack of maintenance are among the potential pitfalls faced when building and implementing a bike share system.

For a bike program to be successful it is important that the correct technology and package of services involved be mated to the unique challenges that each program faces. Furthermore, there needs to be the political will and also the necessary infrastructure for safe cycling. It is therefore recommended that each city considering implementation of a bike share program have an independent assessment of the political backing, community needs, economics, technologies, logistical issues, service area, infrastructure and other challenges faced by a final system.

Figure 1 BSS steps.

Figure 2 Pictures of the BSSs (David Rojas). (A) Marrakesh, Morocco, (B) Melbourne, Australia, (C) Fort Collins, United States (D) Mexico City, Mexico.

A key aspect of any bike share program is system and fleet maintenance and management. These activities can help to ensure the bike share system is in top operating order and sufficient bikes are available to accommodate all users. To ensure that bicycles are available at all stations, it is likely that bicycles will have to be redistributed from one station to another from time to time. Past performance of systems in Lyon and Paris indicates that many locations experience peak times of business when a rack will be either completely full or completely empty, making the rental or return of bikes impossible. Information about bicycle demand should be gathered through GPS units, radio frequency identification (RFID) tags and any other means used to track bicycle locations.

Innovative dockless mobile public-bikesharing programs have the potential to bring cycling back to places where cycling was common before but disappeared like China (Fig. 3). On the basis of GPS travel data from their bikes and a survey of more than 100,000 Mobike users, by April 2017—less than a year after the company's launch in Shanghai, China—Mobike Global estimated that of all journeys made by their users, the percentage of journeys by bicycle had increased from 5.5% to 11.6% (with the majority of journeys done to link with buses and trains) and the number of car journeys had halved (Ding et al., 2018).

However, mobile public-bike-sharing programs without docking stations are inherently subject to vandalism, misuse, and loss of bicycles. Cluttering of footpaths with bicycles and increasing traffic violations by cyclists have also been frequently reported. Despite

Figure 3 Dockless bikesharing system in Singapore (David Rojas).

the problems and challenges, mobile public-bike-sharing programs exemplify an alignment between private-sector interests and public health and sustainability, and offer unique opportunities to promote physical activity on a large scale. By the end of 2017, mobile public-bikesharing programs had spread to hundreds of cities across Asia, Europe, North America, and Australia, but unfortunately failed in many places due to competition, the abandoned bikes and lack of a sustainable business model.

BSSs may help normalize the image of cycling and reduce perceptions that cycling is “risky” or “only for sporty people.” Goodman et al. (2014) sought to compare the use of specialist cycling clothing between users of the London bicycle sharing system (LBSS) and cyclists using personal bicycles. They observed 3594 people on bicycles at 35 randomly selected locations across central and inner London. The 592 LBSS users were much less likely to wear helmets (16% vs. 64% among personal-bicycle cyclists), high-visibility clothes (11% vs. 35%) and sports clothes (2% vs. 25%). In total, 79% of LBSS users wore none of these types of specialist cycling clothing, as compared to only 30% of personal bicycle cyclists. This was true of male and female LBSS cyclists alike. They concluded that bicycle sharing systems may not only encourage cycling directly, by providing bicycles to rent, but also indirectly, by increasing the number and diversity of cycling “role models” visible.

Health Benefits of BSSs

It is well known that cycling is healthy due to physical activity. A number of studies have assessed the health implications of BSSs. As epidemiological studies are hard to conduct, they have mainly used health impact assessment methodology and have taken into account not only health benefits coming from physical activity but also risks from increased inhalation of air pollution and accidents.

The first to do so were Rojas-Rueda et al. (2011) in Barcelona (Fig. 4). They estimated the risks and benefits to health of travel by bicycle, using a bicycle sharing scheme, compared with travel by car in an urban environment in the new public bicycle sharing initiative, Bicing, in Barcelona, Spain (Fig. 5). At the time, the system had 181,982 subscribers. The primary outcome measure was all cause mortality for the three domains of physical activity, air pollution (exposure to particulate matter $<2.5 \mu\text{m}$ (PM_{2.5})), and road traffic incidents. The secondary outcome was change in levels of carbon dioxide emissions. Compared with car users the estimated increase annual change in mortality of the Barcelona residents using Bicing ($n = 181,982$) was 0.03 deaths from road traffic incidents and 0.13 deaths from air pollution. As a result of physical activity, were estimated 12.46 avoided deaths (benefit:risk ratio 77). Overall, taking to account risk and benefits, the total estimated health impact of the Bicing in Barcelona was 12.28 annual deaths avoided. As a result of journeys by Bicing, annual carbon dioxide emissions were reduced by an estimated 9,062,344 kg.

Woodcock et al. (2014) modeled the impacts of the bicycle sharing system in London on the health of its users (Fig. 5). They used total population operational registration and usage data for the London cycle hire scheme (collected April 2011–March 2012), surveys of cycle hire users (collected 2011), and London data on travel, physical activity, road traffic collisions, and particulate air pollution (PM_{2.5}) (collected 2005–12). Over the year examined the users made 7.4 million cycle hire trips (estimated 71% of cycling time by men). These trips would mostly otherwise have been made on foot (31%) or by public transport (47%). They found that the population benefits from the cycle hire scheme substantially outweighed harms (net change -72 DALYs (95% credible interval -110 to -43) among men using cycle hire per accounting year; -15 (-42 to -6) among women; note that negative DALYs represent a health benefit). When they modeled cycle hire injury rates as being equal to background rates for all cycling in central London, these benefits were smaller and there was no evidence of a benefit among women (change -49 DALYs (-88 to -17) among

Figure 4 General framework used by health impact assessments on BSSs.

Figure 5 BSSs in Barcelona, Spain and London, UK. (David Rojas). (A) Barcelona, Spain. (B) London, UK.

Figure 6 Twelve European BSSs included in the health impacts assessment.

men; -1 DALY (-27 to 12) among women). This sex difference largely reflected higher road collision fatality rates for female cyclists. At older ages the modeled benefits of cycling were much larger than the harms. Using background injury rates in the youngest age group (15–29 years), the medium term benefits and harms were both comparatively small and potentially negative.

Otero et al. (2018) performed a multinational health impact assessment study to quantify the health risks and benefits of car trips substitution by bikes trips (regular-bikes and/or electric-bikes) from European BSS with >2000 bikes (Fig. 6). This one was the first health impact assessment including the impact of electric bicycles, taking into account the differences between physical activity, speed, and injury risk compared to regular-bikes. Four scenarios were created to estimate the annual expected number of deaths (increasing or reduced) due to physical activity, road traffic fatalities, and air pollution (Fig. 7). A quantitative model was built using data from transport and health surveys and environmental and traffic safety records. In addition, an economic assessment was included to translate mortality impacts in economic values using the value of statistical life. The study population was adult BSS users between 18 and 64 years old. Twelve BSSs (Barcelona, Brussels, Hamburg, Lille, Lyon, Madrid, Milan, Paris, Seville, Toulouse, Valencia, and Warsaw), were included in the analysis. The study found that between those 12 larger BSS in Europe the car substitution impact was very low (ranging from 4.5% to 12% of the BSS trips). In all scenarios and cities, the health benefits of physical activity outweighed the health risk of traffic fatalities and air pollution, with a ranged benefit:risk ratio of 9 (Milan) and 204 (Seville). It was estimated that 5.17 (95%CI: 3.11–7.01) annual deaths are avoided in the 12 BSSs, with the actual level of car trip substitution, corresponding to an annual saving of 18 million of Euros. It was also estimated that if all BSS trips replaced car trips, 73.25 deaths could be avoided each year (225 million Euros saving) in the 12 cities.

E-Bikes and Bike Sharing

E-bikes or electric bikes are also used as part of the bike sharing fleets in some cities (Fig. 8). Electric bikes can be classified in two different types, “standard assistance” e-bikes, and “high-assistance” e-bikes. Each type of e-bikes is related with different physical activity assistance and speed. The “standard assistance” e-bike is the most common type. In terms of physical activity, “standard assistance” e-bikes can be defined as an e-bike that requires 90% of the physical activity of a regular-bike, and “high assistance” e-bike was defined as an e-bike that requires 75% of the physical activity of a regular-bike (Otero et al., 2018). In terms of speed, “standard assistance” e-bikes were defined as an e-bike that increases in average 21% the speed of a regular-bike, and “high assistance” e-bike was defined as an e-bike that increases on average 33% the speed of a regular-bike (Otero et al., 2018). For traffic fatalities, e-bikes

Figure 7 Deaths per 100,000 cyclists related to the health risks (road traffic fatality and air pollution inhalation) and benefits (physical activity).

have been related to different levels of risk compared to regular bikes. Otero I. et al. reported an odds ratio of 1.92 (1.48–2.48) for traffic fatalities compared with a regular-bike, that means 92% more probabilities to suffer a traffic fatality in an e-bike vs. a regular bike. In their analysis, Otero I. et al. compared risk and benefits of e-bikes. This study estimated that although the electric bikes resulted in less health benefits, compared to the regular-bikes, electric bikes trips still providing more health benefits than traveling by car in those cities.

Helmets and Bike Sharing

The use of bicycle helmets to prevent or reduce serious head injuries is well established. However, it is unclear how to effectively promote helmet use, particularly in the context of bicycle-sharing programs. The bike sharing programs have the potential to increase physical activity and decrease air pollution, but anecdotal evidence suggests helmet use is lower among users of bicycle-sharing programs than cyclists on private bicycles. Kraemer et al. (2012) conducted a cross-sectional study to assess helmet use among users of a bicycle-sharing program in Washington, DC. Helmet use was significantly lower among cyclists on shared bicycles than private bicycles, highlighting a need for targeted helmet promotion activities.

Grenier et al. (2012) described bicycle helmet use among Montreal cyclists as a step toward injury prevention programming. Using a cross-sectional study design, cyclists were observed during 60-min periods at 22 locations on the island of Montreal. There were 1–3 observation periods per location. Observations took place between August 16 and October 31, 2011. A total of 4789 cyclists were observed. The helmet-wearing proportion of all cyclists observed was 46% (95% CI 44–47). Women had a higher helmet-wearing proportion than men (50%, 95% CI 47–52 vs. 44%, 95% CI 42–45, respectively). Youth had the highest helmet-wearing proportion (73%, 95% CI 64–81), while young adults had the lowest (34%, 95% CI 30–37). Visible minorities were observed wearing a helmet 29% (95% CI 25–34) of the time compared to Caucasians, 47% (95% CI 46–49). BIXI (bike sharing program) riders were observed wearing a helmet 12% (95% CI 10–15) of the time compared to riders with their own bike, 51% (95% CI 49–52). They concluded that although above the national average, bicycle helmet use in Montreal was still considerably low given that the majority of cyclists did not wear a helmet.

In a pilot study, Basch et al. (2014) estimated the prevalence of helmet use among a sample of Citi Bike program users in New York City. A total of 1054 cyclists were observed over 44 h and across the 22 busiest Citi Bike locations. Overall, 85.3% (95% CI 82.2, 88.4%) of the cyclists observed did not wear a helmet. Rates of helmet non-use were also consistent whether cyclists were entering or leaving the docking station, among cyclists using the Citi Bikes earlier versus later in the day, and among cyclists using the Citi Bikes on weekends versus weekdays. Improved understanding about factors that facilitate and hinder helmet use is needed to help reduce head injury risk among users of bicycle sharing programs.

Basch et al. (2015) studied the NYC's public bicycle share program, Citi Bike, the fastest growing program of its kind in the US, with nearly 100,000 members and more than 330 docking stations across Manhattan and Brooklyn. The purpose of this study was to assess helmet use behavior among Citi Bike riders at 25 of the busiest docking stations. The 25 Citi Bike Stations varied greatly in terms of usage: total number of cyclists ($N = 96$ –342), commute versus recreation (22.9%–79.5% commute time riders), weekday versus weekend (6.0%–49.0% weekend riders). Helmet use ranged between 2.9% and 29.2% across sites (median = 7.5%). A total of 4919 cyclists were observed, of whom 545 (11.1%) were wearing helmets. Incoming cyclists were more likely to wear helmets than outgoing cyclists (11.0% vs 5.9%, $P = .000$). NYC's bike share program endorses helmet use, but relies on education to encourage it. The data confirmed that, to date, this strategy has not been successful.

Mooney et al. (2019) counted cyclists over several hours at four locations in Seattle, WA. They categorized each rider according to whether he or she was wearing a helmet and to whether or not he or she was riding a bike share bike. Whereas 91% of riders of private bikes wore helmets, only 20% of bike share riders wore helmets. Moreover, in locations where a greater proportion of riders were on bikes share bikes, fewer riders of private bicycles wore helmets ($r = -0.96$, $P = 0.04$). The impact of bike sharing programs on helmet wearing norms among private bike riders warrants further exploration, but integration of bike helmet in the BSS could be an option to encourage bike helmet use among BSS users (Fig. 9).

BSS Users' Profiles

Ogilvie and Goodman (2012) sought to examine inequalities in uptake and usage of London's Barclays Cycle Hire (BCH) scheme. They obtained complete BCH registration data, and compared users with the general population. They examined usage levels by explanatory variables including gender, small-area income-deprivation and local cycling prevalence. 100,801 registered individuals made 2.5 million trips between July 2010 and March 2011. Compared with residents and workers in the central London area served by the scheme, registered individuals were more likely to be male and to live in areas of low deprivation and high cycling prevalence. Among those registered, females made 1.63 (95% CI 1.53, 1.74) fewer trips per month than males, and made under a fifth of all trips. Adjusting for the fact that deprived areas were less likely to be close to BCH docking stations, users in the most deprived areas made 0.85 (95% CI 0.63, 1.07) more trips per month than those in the least deprived areas. They concluded that females and residents in deprived areas were underrepresented among users of London's public bicycle sharing scheme. The scheme's planned expansion into more deprived areas has, however, the potential to create a more equitable uptake of cycling.

Figure 9 Helmet included in the Medina BSS in Marrakesh, Morocco (David Rojas).

Hosford et al. (2018) examined the socio-demographic and transportation characteristics of current, potential, and unlikely users of a public bicycle share program and identified specific motivators and deterrents to public bicycle share use. They used cross-sectional data from a 2017 Vancouver public bicycle share (Mobi by Shaw Go) member survey ($n = 1272$) and a 2017 population-based survey of Vancouver residents ($n = 792$). They categorized nonusers from the population survey as either potential or unlikely users based on their stated interest in using public bicycle share within the next year. Public bicycle share users in Vancouver tended to be male, employed, and have higher educations and incomes as compared to nonusers, and were more likely to use active modes of transportation. The vast majority of nonusers (74%) thought the public bicycle share program was a good idea for Vancouver. Of the nonusers, 23% were identified as potential users. Potential users tended to be younger, have lower incomes, and were more likely to use public transit for their main mode of transportation, as compared to current and unlikely users. The most common motivators among potential users related to health benefits, not owning a bicycle, and stations near their home or destination. The deterrents among unlikely users were a preference for riding their own bicycle, perceived inconvenience compared to other modes, bad weather, and traffic. Cost was a deterrent to one-fifth of unlikely users, notable given they tended to have lower incomes than current users.

Conclusions

BSSs have gained popularity over the recent years and can now be found in many cities around the World. Different technological improvements have been implemented (electric bikes, dockless, etc.) make it more attractive and easier for users. Although often introduced to reduce congestion and for climate mitigation reasons, they have only been able to absorb a small portion of car trips across cities. Despite the small impact on mode shift, they have been able to provide many health and health economic benefits, due to the increase of physical activity, and helping to normalize urban cycling through cities. BSSs are facing many challenges and opportunities, that should be tackle to improve their health benefits, such as provide more equally distributed bikes throughout the population, increase the use of helmets, and being able to attract more users from private motorized modes like cars or motorcycles. In general, BSSs should be seeing as a tool for public health promotion and prevention.

Introduction

The use of E-bikes have seen a rapid growth during the last few decades. In Europe, the numbers of e-bikes increased from 588,000 in 2010 to 1,667,000 in 2016 (CONEBI, 2017).

Compared to conventional bicycles, e-bikes can maintain speed with less physical effort due to the electric-motor support, hence overcoming some of the common barriers to cycle commuting (De Geus and Hendriksen, 2015). However, given that e-bikes require less muscular effort, the question then is if the pedaling is sufficiently strenuous to give health benefits, and most importantly, what the public health effects are from them.

Definitions

E-Bikes

In general, e-bikes in a European, North American, and Australian context refers to bicycle-style e-bike design (i.e., the bicycle has functional pedals, but is assisted with an electric motor) as opposed to scooter-style e-bike design (with no pedals) (Fishman and Cherry, 2016). E-bikes following the regulations made by the European Union are formally known as electric pedal assisted cycle (EPAC), but are also known as pedelecs. The EU regulations states that the motor assistance is limited to 250 W, and caps assistance at 25 km/h (European Committee for Standardization, 2011). Pedelecs are in most countries legally classified as bicycles, as they require pedaling for electrical assistance to be provided (Fishman and Cherry, 2016). In the following we use the term *e-bike* to denote a bicycle of the pedelec type.

Physical Activity

Physical activity (PA) from cycling is defined as any bodily movement produced by skeletal muscles that requires energy expenditure (Warburton and Bredin, 2017). It has both an acute and long term effect, and reduces risk of several noncommunicable diseases (Warburton and Bredin, 2017). In general, too little physical activity can have a negative effect on health, and increase the risk of diseases such as heart attack, cancer and diabetes (Bauman, 2004; Warburton and Bredin, 2017). The intensity of an activity can be measured by means of oxygen uptake, metabolic equivalents, energy expenditure per minute, heart rate and power output (Åstrand and Rodahl, 2003). Physical activity is normally categorized as low, moderate, and vigorous intensity.

The health benefits of physical activity depends on the individual's baseline cardiorespiratory fitness (i.e., weight, maximal O_2 uptake, etc.) and the frequency, duration, and intensity of the activity performed (Gjerset, 1992). Maximal oxygen uptake ($VO_{2\text{-max}}$) is the amount of oxygen that the body can utilize in 1 min.

To gain health benefits, The World Health Organization (WHO) recommends that healthy adults engage in at least 150 min of moderate physical activity or 75 min of vigorous physical activity per week (World Health Organization, 2016). Behind these recommendations lies an understanding of the physiological mechanisms in which the higher the intensity, the shorter the duration

Table 1 Categories of MET levels and related activities

<i>MET</i>	<i>Physical activity</i>	<i>Examples</i>
Below 3	Light	Sitting, walking slowly
3–6	Moderate	Walking, housework
6 and above	Vigorous	Cycling, jogging, aerobics

MET, Metabolic equivalent of the task.

is needed for the same health gain. If an individual has a “low” baseline fitness, less duration, frequency and/or intensity is needed for enhanced health effect (Gjerset, 1992; Åstrand and Rodahl, 2003).

Metabolic Equivalent of the Task

In order to have an objective measure of physical activity we often refer to the Metabolic equivalent of the task (MET), which is an objective measure of rate of energy use relative to the person’s mass. One MET is defined as the energy used at rest (resting metabolism). **Table 1** shows categories of MET levels and related activities.

To be intense enough to promote and maintain health an exercise should be at least three METs, which is threshold for moderate intensity (Haskell et al., 2007).

Active Transport and Health Benefits

In many countries, there is an aim to increase cycling as a mode of transport. One reason for this is the potential for overall increased physical activity and subsequent population health benefits (Oja et al., 2011). Increasing physical activity levels through active transport can potentially give many individuals an adequate level of PA (Ainsworth et al., 2011; de Geus et al., 2007). Active commuting has been found to be associated with a lower risk of all-cause mortality and cancer incidence (Celis-Morales et al., 2017). The greatest gains in health outcomes from active travel are reported in the least active individuals (Oja et al., 2011).

Intensity of Physical Activity From Using E-Bikes

Several studies have compared power expenditure when cycling on an e-bike with a conventional bike (CB) (e.g., Berntsen et al., 2017; Gojanovic et al., 2011; Theurel et al., 2012), using different research designs and physiological measures. Typically, all of these studies find that people spend less energy and less time when riding an e-bike than a conventional bike for the same trip. As an example, a study where subjects performed trips at a self-selected pace ($N = 18$) found that VO_2 max during cycling with an e-bike (high assistance) was 55%, compared to 66% for an e-bike (standard assistance) and 73% for a conventional bike (Gojanovic et al., 2011).

The differences between e-bikes and CBs are most evident uphill (Berntsen et al., 2017; Gojanovic et al., 2011; Langford et al., 2017), which illustrates an interesting case of adaptation among users. When allowed to self-select pace and intensity, people may select a similar physiological intensity across activities regardless of the assistance (conventional bike vs e-bike), thereby resulting in similar physiological outcomes on flat and downhill segments. Since there is a lower threshold for how slowly the conventional bike can be ridden without losing balance, there is less opportunity to adjust effort levels to produce comparable intensity levels, when riding uphill.

A systematic review by Bourne et al. (2018) shows that even if e-bikes demand less effort than CBs, they do help to provide at least moderate intensity. Importantly, this finding is not dependent upon baseline activity levels: both active and inactive individuals get some exercise.

E-Bikes and Cardiorespiratory Fitness Improvement

Cycling on a regular basis (at least three times a week) with a conventional bike positively influences physical fitness (de Geus et al., 2009; Hendriksen et al., 2000; Moller et al., 2011; Oja et al., 2011). Given that e-bike users spend less energy than conventional bike users, the question then is, can e-bikes improve people’s cardiorespiratory fitness?

The above-mentioned studies indicate that there is potential. The percentage of peak $VO_{2\text{-max}}$ (i.e., the maximum amount of oxygen that the body can make use of in one minute) are found to range from 51 to 75 for e-cycling (Bourne et al., 2018). These values exceed the hypothesized minimum of threshold (45% of $VO_{2\text{-max}}$) required to improve cardiorespiratory fitness (Swain and Franklin, 2002).

Intervention studies have looked at e-cycling in a population over time (De Geus et al., 2013; Höchsmann et al., 2018; Lobben et al., 2018; Peterman et al., 2016). Peterman et al. (2016) conducted a study with 20 sedentary commuters, and found that after four weeks of e-bike commuting participants improved their glucose tolerance, VO_2 max (8% increment), and maximal power output. These results indicate that for inactive individuals, cardiorespiratory fitness could be improved.

However, since only a few of these studies included control groups, the number of participants tended to be quite low and study periods were limited, more research is needed to give firm conclusions about the long-term health impacts.

Substitution Effects

A key issue from a public health perspective is whether the health effect of increased cycling is cancelled out by a reduction in other physical activities—a *substitution effect* (Thomson et al., 2008).

In transport planning, cost benefit analysis (CBA) is a central tool. In a CBA all the measurable benefits of a given measure or investment are weighed against its cost. When planning investments for better cycling infrastructure, health benefits account for a large portion of the total benefits; as much as 55%–75% according to Slensminde (2004). However, one large question that is unresolved is the size of the substitution effect. In general, the empirical evidence for substitution is weak (Thomson et al., 2008).

Evidence seems to indicate that people have a total “time budget” from which increased time spent traveling would imply decreased time spent on other activities (Börjesson and Eliasson, 2012). If this is the case, people are likely to have a total (physical or psychological) “budget” for PA, and that increased cycling (with conventional bikes) would cause physical or mental fatigue affecting engagement in other activities negatively. However, this study was based on hypothetical self-reports, which arises some questions about the validity of the results. The finding is also somewhat counter to general knowledge from behavior and motivational impacts, that indicates that conducting one positive activity might entice people to conduct positive behavior in other health domains (Mata et al., 2009; Sniehotta et al., 2005).

Even if people do have a time-budget, e-bikes in particular might play a different role in such an equation than CBs, given that they require less energy and might not spend so much of the total “PA-time budget”. Further to this, active transport might have larger public health benefits than the typical infrequent higher intensity activities it replaces (Praznocy, 2012).

Some studies have assessed e-bikes and substitution effects. Castro et al. (2019) found physical activity (measured as MET minutes per week) from travel-related activities to be similar for e-bike and CB, implying that e-bikers does not necessarily reduce other PA. An intervention study found that for those starting to use an e-bike other physical activity was not significantly affected, that is indicating no substitution effect (Sundfør and Fyhri, 2017).

Effects on Travel Behavior

A person who buys an e-bike and takes up cycling will increase his or her physical activity levels, if this cycling does not substitute an evening gym class or a run around the park. So from a public health perspective increased cycling from e-bikes would in itself constitute a positive physical activity result.

But from a transport policy perspective, we are not really interested in generating more transport, but in replacing nonsustainable or passive transport with active and sustainable transport. From this perspective, replacing your regular trip on a conventional bicycle with an e-bike has a negative health effect, given no other adjustment. Only when people replace a passive mode of transport (i.e., car or public transport) will there be a positive health benefit, as the energy expenditure (indicated by METs) is higher when riding an e-bike compared to sitting still. So from the perspective of active mobility we are interested in knowing what travel modes e-bike replace. Rather than just looking at new trips, we are looking at travel mode share changes.

A review by Cairns et al. (2017) looking at e-bikes’ mode change effect found that proportion of car journeys being replaced by bike journeys ranged from 16% to 76%. A challenge with many studies looking at mode change is that they are either retrospective (i.e., people report previous travel behavior after they have purchased an e-bike) or cross-sectional (comparison of e-bike users with non-users at one time-point), thus giving little control over confounding factors. Kroesen (2017) found that e-bike users cycled 3.0 km a day, compared to 2.6 km a day for conventional cyclists, and also travel less with car than conventional cyclists.

A study using panel data from the Dutch Mobility survey, compared travel patterns for people who have bought an e-bike between two time periods ($N = 107$). The results of this study confirms previous findings: e-bike users reduce their share of conventional cycling, increase their total amount of cycling and reduce their amount of car driving (Sun et al., 2020).

In two studies conducted in Norway people using an e-bike were compared to a control group without access to an e-bike. In the first study, 60 participants were allowed to borrow the e-bikes for 2 or 4 weeks. The trial group increased their total bicycle use, and saw a twofold increase in cycling as share of all travel (Fyhri and Fearnley, 2015).

The large change in cycling previously observed in schemes and more hypothetical research designs was also replicated with actual customers. In the second study people who bought an e-bike ($N = 39$) were compare to a group wanting to buy one ($N = 142$) as well as broader comparison group ($N = 767$). People who purchased an e-bike increased their bicycle use from 2.1 to 9.2 km/day on average, representing a change in bike as share of all transport from 17% to 49%. An important point with this study is that the control groups also had an increase in their cycling activity during the study period (due to seasonal differences). But statistical tests showed that this increase was far lower than the observed changes for the people who had bought an e-bike.

Psychological Outcomes From Riding an E-Bike

Cycling to work on a conventional bike gives more positive affect and enjoyment compared to other modes of travel (Gatersleben and Uzzell, 2007; Rissel et al., 2016). One reason for this is that cycling happens outdoors and often in green space, which has been proven to be of benefit for mental restoration (Barton and Pretty, 2010). Combining physical activity and nature experiences might also work together to create a synergetic effect on health (Barton and Pretty, 2010). It has also been suggested that cycling to work improve vitality, cognitive performance and work capacity (Calogiuri et al., 2016). Other suggested benefits from active commuting are (1) Greater extent of commuting control and “arrival-time reliability”; (2) Sensory stimulation reaching enjoyable levels; (3) The mental effects of moderate intensity physical activity making one feel better; and (4) More likely for social interaction to occur (Wild and Woodward, 2019).

There are a few studies that have looked specifically at e-bikes and psychological outcomes. Page and Nilsson (2017) found that people who change their behavior to active commuting by e-bike report more positive affect, better physical health and more productive organizational behavior, compared with passive commuters. Some studies report enjoyment and positive experiences of the user (Fyhri and Fearnley, 2015; Plazier et al., 2017; Popovich et al., 2014), as well as favorable effects on mental well-being (Jones et al., 2016), and others conclude that due to the decreased amount of effort needed, it might be easier to concentrate (Theurel et al., 2012). However, few controlled studies have been performed and the evidence of psychological health benefits is inconclusive (Bourne et al., 2018).

Accident Risk From E-Bikes

In general, bicycles have a higher accident risk than most other modes of transport (Elvik and Vaa, 2005). Some have raised the concern that e-bikes are even more dangerous than conventional bikes, and that promoting them will lead to more accidents. When discussing this claim it is important to distinguish between a mere *exposure effect*, differences in *injury severity* and finally an *increased risk* and.

The exposure effect has to do with the question about whether people with e-bikes cycle more than people with CBs, and by this are more exposed to the risk of being a cyclist in traffic.

There have been some studies investigating if e-bikes have more accidents. Surprisingly few of these have made account for exposure differences. For example, an Israeli study went as far to advise against e-bikes based on an observed increase in accident figures (Siman-Tov et al., 2017). However, this study did not take into account possible changes in number of e-bikes in traffic during the study period. Also, as we have seen, people tend to ride longer when they switch from a conventional bike to an e-bike.

Another limitation of this study, as with many other studies, is that they are based on official injury data, or trauma registers. Even if these data have the advantage of following a strict protocol when an accident is defined, they only cover a small share of all accidents. Since, underreporting of bicycle accidents is well known, typically only 10% of bicycle traffic accidents are reported in official figures (Bjørnskau, 2005; Shinar et al., 2018), this implies that only the most serious accidents are included. Related to this, the question then is whether e-bikes lead to more *severe accidents*. Part of the reasoning behind this hypothesis is that they are heavier, and also that they can keep a higher speed. Most studies looking at injury severity conclude that there is no difference between e-bikes and conventional bike (Otte et al., 2014; Papoutsi et al., 2014; Weber et al., 2014).

Some early studies have indicated and increase in *accident risk* for e-bikes (Schepers et al., 2014), but later studies have not replicated this (Schepers et al., 2018; Weiss et al., 2018). A study, carried out in Norway ($N = 7752$), combined three data sets to compare conventional and electric bicycles, while at the same time controlling for age, gender and exposure (Fyhri et al., 2019). The study found an overall risk increase for e-bike users, but suggests that all of this risk can be attributed to female cyclists. In other words, women have a higher risk on e-bikes, whereas men do not. Men have a higher total risk. According to the study some of this risk increase can be attributed to experience with the bicycle. In other words, women are more likely to be inexperienced cyclists than men, and since they also are more likely to take up cycling with an e-bike, this will inevitably lead to more accidents. Future research should investigate if this is just a transitory effect, or if there is the risk difference is maintained even after e-bikes have been around for a while.

For conventional bicycles the health benefit of increased physical activity accumulated though cycling outweighs the risk of injuries (Andersen et al., 2018; De Hartog et al., 2010; WHO, 2019). Given that the overall risk lever for e-bikes is not higher than that of CBs, it seems safe to conclude that the same will hold for e-bikes, as well.

E-Bikes and Health Summarized

Physical activity is good for your health, and active travel can increase the total amount of physical activity you conduct during a day. The role the e-bike plays in this equation is not totally clear, but the evidence leans to the positive side. For the same pace and distance, an e-bike user will have less exercise than a conventional cyclist, due to the assistance of the electrical motor. Riding an e-bike will give different health gains for people who normally are inactive than people who are used to being active. Still, evidence shows that the e-bike provides physical activity at a moderate intensity level, regardless of baseline activity level.

The most important factor to consider when looking at the e-bike from an active mobility perspective is what transport mode it replaces. Second to that is the potential substitution effect. If people switch from a passive mode of transport to e-bikes this would imply an increase in physical activity levels. If, however, the e-bike replaces a conventional bike, physical activity will decrease. Evidence so far indicate that people with e-bike increase their amount of cycling compared to a situation where they do not have access to an e-bike. Longitudinal studies should be conducted to confirm this. Even if some of this cycling replaces former walking or conventional bike trips, the total time spent on active mobility is increased. Other physical activity is not significantly affected when starting to use an e-bike, implying no substitution effect.

The e-bike seems to cater for novice cyclists and increases the likelihood that these individuals take up and maintain cycling. It could also attract groups where the conventional bike is not seen as an option, such among elderly and sedentary individuals.

One challenge that then arises is that their lack of previous cycling experience might be a risk factor. Even if the balance of the evidence now points to no overall risk difference between e-bikes and CBs, there might be an elevated risk for novice riders, who often happen to be female. The health benefit of increased physical activity accumulated through cycling (with any bike) is normally considered as higher than the negative outcome from injuries.
